Figure 6 quantifies the performance of the additional FVD for increasing levels of the seismic input, i.e., PGA $a_g = 0.10\text{ g}$ (low intensity), $a_g = 0.25\text{ g}$ (moderate earthquake), and $a_g = 0.40\text{ g}$ (strong motion). It is evident that in all the three cases, the FVD allows mitigating the seismic response. Due to the highly nonlinear behavior of the selected device, however (i.e., the small velocity exponent $\alpha = 0.3$), this retrofitting technique is more efficient in case of low intensity, that is, the lower the PGA, the higher the

percentage reduction in displacements and accelerations.

Elastomeric Viscoelastic Dampers (EVDs)

Viscoelastic damping is another mechanism of energy dissipation which has been successfully used to improve the dynamic behavior of structures (e.g., Zhang and Soong 1992; Chang et al. 1995; Singh and Moreschi 2002; Park et al. 2004). Historically, one of the first and most impressive applications is the use of

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 5 (continued)

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 5 Effect of the period of vibration. Seismic response of SDOF oscillators with different periods of vibration $T_i = 0.3$ s (top row), 0.5 s

(central row), and 0.8 s (bottom row), in terms of time history of displacement (first column), hysteresis loop (second column), energy dissipated (third column) and floor spectra (fourth column)

10,000 elastomeric viscoelastic dampers (EVDs) in each of the Twin Towers of the World Trade Center (1968–2001) for mitigating the wind-induced vibrations, which otherwise would have been excessive. Because the amount of energy that can be dissipated through viscoelastic damping is comparatively smaller than for fluid viscous dampers and steel hysteretic dampers, EVDs are mainly used for wind engineering applications, although they can also be effective for the seismic retrofit of existing structures.

Figure 7, for instance, shows an application of EVDs, in which the devices are mounted as part of chevron steel braces externally connected to the main structural frame. In this way, energy is dissipated through the shear deformations within each EVD (Fig. 7a), which in turn are caused by the relative movements of the stories.

From a mathematical point of view, the reaction force experienced by a linear viscoelastic device at rest for $t \leq 0$ can be expressed in the time domain through the following convolution integral:

$$f_{\text{EVD}}(t) = \int_0^t \varphi_{\text{EVD}}(t-s) \dot{u}(s) ds, \quad (15)$$

where $\varphi_{\text{EVD}}(t)$ is the relaxation function of the damper, representing the time history of the reaction force due to a unit-step displacement; and $\dot{u}(t)$ is the relative velocity between the two ends of the device. One can easily prove that elastic stiffness and viscous damping are particular cases of the viscoelastic behavior. If the relaxation function for the elastic behavior is a Heaviside's step function of amplitude k

$$\varphi_{\text{EVD}}(t) = k\Theta(t), \quad (16)$$

where $\Theta(t) = 0$ for $t < 0$; $1/2$ for $t = 0$; 1 for $t > 0$, then substituting Eq. 16 into Eq. 15 gives

$$\begin{aligned} f_{\text{EVD}}(t) &= \int_0^t k\Theta(t-s) \dot{u}(s) ds \\ &= k \int_0^t \dot{u}(s) ds = ku(t), \end{aligned} \quad (17)$$

which is the constitutive law of a linear-elastic spring of stiffness k . Similarly, if the relaxation

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 6 (continued)

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 6 Effect of the intensity of the ground shaking. Seismic response of SDOF oscillators with different values of PGA $a_g = 0.10 \text{ m/s}^2$ (top

row), 0.25 m/s^2 (central row), and 0.40 m/s^2 (bottom row), in terms of time history of displacement (first column), hysteresis loop (second column), energy dissipated (third column) and floor spectra (fourth column)

function is taken as a Dirac's delta function of intensity c

$$\varphi_{\text{EVD}}(t) = c\delta(t), \quad (18)$$

where $\delta(t) = \dot{\Theta}(t)$, Eq. 15 then simplifies as:

$$f_{\text{EVD}}(t) = \int_0^t c\delta(t-s)\dot{u}(s)ds = c\dot{u}(t), \quad (19)$$

which is the constitutive law of a linear-viscous dashpot of damping coefficient c .

In general, the relaxation function is zero for $t < 0$ (this ensures the causality of the constitutive law) and monotonically decreasing for $t \geq 0$. For structural dampers made of natural rubber or other elastomeric materials, the relaxation function can be accurately represented as the superposition of a certain number N of exponential functions with various rates of decay, that is:

$$\varphi_{\text{EVD}}(t) = \left[\sum_{\ell=1}^N R_{\ell} \exp(-t/\tau_{\ell}) \right] \Theta(t), \quad (20)$$

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 7 Elastomeric viscoelastic dampers. Devices as installed in the seismic retrofit of the Gentile-Fermi School in Fabriano, Italy (Courtesy of

FIP Industriale, Prof Rodolfo Antonucci and Francesco Balducci); detail of the damper (a) and installation with external chevron braces (b)

where the N pairs $\{R_\ell, \tau_\ell\}$ define the discrete relaxation spectrum of the EVD, in which the rigidity coefficient R_ℓ gives the amplitude of the ℓ th contribution, while the relaxation time τ_ℓ provides a measure of the time required by such term to vanish (i.e., the larger the relaxation time, the slower the relaxation process). It is worth noting here that for $\tau_\ell \rightarrow +\infty$, the ℓ th contribution in the r.h.s. of Eq. 20 becomes purely elastic; similarly, the pure viscous behavior is recovered for $\tau_\ell \rightarrow 0$. Any intermediate value of the relaxation time determines a truly viscoelastic behavior, which combines stiffness and energy dissipation.

Interestingly, one can prove that Eq. 20 is the relaxation function of N Maxwell's elements in parallel, i.e., a set of N parallel elastic springs R_ℓ each one connected in series with a viscous dashpot $D_\ell = R_\ell \tau_\ell$ (see Fig. 8). Accordingly, the reaction force can be expressed as (Palmeri et al. 2003; Adhikari and Wagner 2004)

$$f_{\text{EVD}}(t) = \sum_{\ell=1}^N R_\ell \lambda_\ell(t), \quad (21)$$

where $\lambda_\ell(t)$ is the ℓ th additional internal variable associated with the dynamic response of the viscoelastic device, which corresponds to the elastic deformation within the ℓ th Maxwell element and is ruled by

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 8 Generalized Maxwell's model. Spring-dashpot model for EVDs

$$\dot{\lambda}_\ell(t) = \dot{u}(t) - \frac{\lambda_\ell(t)}{\tau_\ell}. \quad (22)$$

Although EVDs used in the engineering practice usually require two or more Maxwell's elements to capture their dynamic behavior, the simplest case of a single Maxwell's element (i.e., $N = 1$) can be effectively used to assess the effects of the relaxation time τ_1 on the seismic performance of a building structure retrofitted with viscoelastic devices. The resulting governing equations for a SDoF oscillator equipped with additional viscoelastic damping then become

$$\begin{cases} \ddot{u}(t) + 2\zeta_0\omega_i\dot{u}(t) + \omega_i^2 u(t) + \underbrace{\frac{R_1}{m}\lambda_1(t)}_{f_{\text{EVD}}(t)/m} = -\ddot{u}_g(t); \\ \dot{\lambda}_1(t) = \dot{u}(t) - \frac{\lambda_1(t)}{\tau_1}, \end{cases} \quad (23)$$

in which the two linear differential equations have to be solved simultaneously.

For this parametric study, ground acceleration $\ddot{u}_g(t)$, undamped periods of vibration $T_i = 2\pi/\omega_i$, and viscous damping ratio ζ_0 are the same as in the previous section; the rigidity coefficient is assumed to be $R_1/m = 0.5 \text{ s}^{-2}$, where m is the mass of the oscillator; three values of the relaxation time have been chosen, namely, $\tau_1 = 0.0136$, 0.136 , and 1.36 s .

In a first stage, the intermediate value of the relaxation time has been used, i.e., $\tau_1 = 0.136 \text{ s}$, and the beneficial effects of the additional viscoelastic damping have been assessed for three periods of vibration, namely, $T_i = 0.3$, 0.5 , and 0.8 s (corresponding to “stiff,” “resonant,” and “flexible” structure, respectively). The comparison between their seismic responses with (solid lines) and without (dashed lines) EVDs is ordinally shown in the three rows of Fig. 9.

Figure 9a–c reveals that in all the three cases, the EVDs are effective in reducing the maximum displacements induced by the ground shaking. Their hysteresis loops (Fig. 9d–f) are ellipses, in which the slope of the major axis increases with the effective stiffness of the device. It is worth stressing here that, while the FVDs considered in the previous section only increase the damping capabilities of the structure, without affecting its stiffness, EVDs have both elastic stiffness and viscous damping. As a result, the retrofitted structure not only is capable of dissipating more energy but is also stiffer. This is confirmed by the floor spectra of Fig. 9j–l, in which the peak of the solid curves (retrofitted system) is always lower (because of the damping) and occurs at a reduced period T_j (because of the increased stiffness).

In a second stage, the effects of the relaxation time τ_1 have been investigated, while keeping

constant the undamped period of vibration ($T_i = 0.5 \text{ s}$). The results of these numerical analyses are offered within Fig. 10, which shows reduced peak displacements in all cases (Fig. 10a–c). Depending on the relaxation time, however, the type of control mechanism provided by the additional EVD can be quite different. In the top row ($\tau_1 = 0.0136 \text{ s}$, Fig. 10a, d, g, j), for instance, the elastomeric device behaves essentially as a linear-viscous damper, while in the bottom row ($\tau_1 = 1.36 \text{ s}$, Fig. 10c, f, i, l), the control force is more similar to an elastic force. A better performance is clearly seen in the central row ($\tau_1 = 0.136 \text{ s}$, Fig. 10b, e, h, k), where the control force is truly viscoelastic: this happens because in this case the timescale for the relaxation of the EVD is comparable to the period of the oscillations, while the relaxation is too fast in the top row ($\tau_1/T_i < 1/20$), too slow in the bottom row ($\tau_1/T_i > 2$).

There are interesting consequences for the different types of control forces exerted by the elastomeric device. In terms of hysteresis loops, for instance, the slope of the major axis of the viscoelastic ellipses in the $f_{\text{EVD}}(t) - u(t)$ diagram increases with the relaxation time τ_1 . In the top row (Fig. 10d), in which the viscous damping prevails, the major axis is substantially horizontal (similar to the linear hysteresis loop for $\alpha = 1$ within Fig. 4a); on the contrary, the steepest slope is seen in the bottom row (Fig. 10f), in which the elastic stiffness prevails, and therefore the ellipse is very narrow (meaning that little energy is dissipated in each cycle). In the central row, where the EVD provides both stiffness and damping, the hysteresis loop has the major axis inclined and shows that a significant amount of energy is dissipated.

It is also interesting to note the differences between the floor spectra for the three cases. While the proper viscoelastic behavior in the central row (Fig. 10k) allows the peak of the floor spectrum to reduce (because of the additional damping) and shift to the left (because of the additional stiffness), only the reduction of the peak is seen in the top row (Fig. 10j) and the peak shift in the bottom row (Fig. 10l).

From the above observations, it follows that the relaxation times of the devices (also in relationship to the periods of vibration) are the key parameters to be considered while designing the seismic retrofitting of an existing structure with EVDs.

Steel Hysteretic Dampers (SHDs)

Plastic deformations in metals can be exploited to dissipate energy and therefore mitigate the

effects of seismic forces. In this case, the device has to be designed in order to maximize the plastic work and ensure stable hysteretic cycles (e.g., Nakashima et al. 1996).

Low-yield steel plates with hourglass and triangular shapes have been proposed, and they are best known with the acronyms ADAS (added viscous and stiffness) and TADAS (triangular ADAS), respectively. Such devices are usually installed at the top of stiff chevron steel braces, so that the relative lateral movement of two consecutive stories induces bending about the weak

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 9 (continued)

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 9 Effect of the period of vibration. Seismic response of SDOF oscillators with different periods of vibration $T_i = 0.3$ s (top row), 0.5 s

(central row), and 0.8 s (bottom row), in terms of time history of displacement (first column), hysteresis loop (second column), energy dissipated (third column) and floor spectra (bottom column)

axis of the steel plate (Xia and Hanson 1992; Chou and Tsai 2002; Alehashem et al. 2008; Bayat and Abdollahzadeh 2011).

Figure 11 (reproduced from Alehashem et al. 2008) shows the typical geometry of ADAS and TADAS devices. In the first case (Fig. 11a), the steel plates are clamped, and their hourglass shape allows maximizing the energy dissipation when the plates experience plastic bending. In the second case (Fig. 11b), the steel plates are clamped at the top and pinned

at the bottom: the bending moment then increases linearly with the height, and the triangular shape then becomes the most efficient one.

Buckling-restrained braces (BRBs), also known as BRADs (buckling-restrained axial dampers), are another type of metal dampers, in which axial rather than bending stresses in low-yield steel are exploited. The system typically consists of a cruciform low-yield pinned steel brace, whose buckling is prevented by encasing the brace within a concrete-filled steel

tube, and a special coat inhibits the bond between inner steel and concrete (so that the brace can freely elongate and shorten in each cycle). This solution is particularly efficient as the brace is subjected to uniaxial stress/strain, and therefore all the volume of material can contribute to energy dissipation (e.g., Sabelli et al. 2003; Black et al. 2004; Di Sarno and Manfredi 2010).

Figure 12 shows the application of this type of devices for the seismic retrofit of two schools with RC framed structure in Italy. In the first case (Fig. 12a), the devices are left exposed (increasing the sense of safety for the occupants),

while in the second case (Fig. 12b), the choice has been to cover the devices.

Many mathematical models have been proposed for the representation of the elastoplastic force experienced by SHDs (steel hysteretic dampers) such as ADAS and BRB devices. The Bouc–Wen model is probably the most popular one, as it can be easily implemented to perform time-history analyses (Bouc 1971; Wen 1976; Ismail et al. 2009). The model requires the introduction of a dimensionless hysteretic variable $z(t)$, which is proportional to the elastoplastic force:

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 10 (continued)

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 10 Effect of the relaxation time. Seismic response of SDoF oscillators with different values of the relaxation time $\tau_i = 0.0136$ s (*top row*),

0.136 s (*central row*), and 1.36 s (*bottom row*), in terms of time history of displacement (*first column*), hysteresis loop (*second column*), energy dissipated (*third column*) and floor spectra (*fourth column*)

$$f_{\text{SHD}}(t) = f_y z(t), \quad (24)$$

and is ruled by the following nonlinear differential equation:

$$\begin{aligned} \ddot{z}(t) = & \frac{1}{\delta_y} \left(\dot{u}(t) - \sigma |\dot{u}(t)| |\dot{z}(t)|^{n-1} \dot{z}(t) \right. \\ & \left. - (1 - \sigma) \dot{u}(t) |\dot{z}(t)|^n \right), \end{aligned} \quad (25)$$

where f_y and δ_y are the yield force and yield displacement of the device, while σ and n are

two dimensionless parameters which control the shape of the hysteretic cycles. That is, the larger $n > 1$, the quicker the transition between elastic and plastic branches, and vice versa (see left column of Fig. 13); the larger $\sigma > 0$, the steeper the slope of the hysteretic loop $f_{\text{SHD}}(t) - u(t)$ when the device reenters the elastic branch (for $\sigma = 0.5$ one obtains the same slope f_y/δ_y as the elastic branch; see right column of Fig. 13).

For the sake of simplicity, the model of Eqs. 24 and 25 assumes that once the plastic

branch has been reached, there is no further increase in the elastoplastic force, i.e., $|f_{\text{SHD}}(t)| \leq f_y$ (elastic-perfectly plastic behavior). If the device shows a residual post-yielding stiffness $k_{\text{d,res}}$, an elastic term can be added to the r.h.s. of Eq. 24, which then becomes:

$$f_{\text{SHD}}(t) = (f_y - k_{\text{d,res}}\delta_y)z(t) + k_{\text{d,res}}u(t). \quad (26)$$

Additionally, degradation effects can also be accounted for through a reduction of the yield

force f_y and the elastic stiffness f_y/δ_y , which in turn can be expressed as functions of the absorbed hysteretic energy:

$$W_{\text{SHD}}(t) = \int_0^t f_{\text{SHD}}(\tau)\dot{u}(\tau)d\tau, \quad (27)$$

i.e., the more hysteretic energy is dissipated, the more damage is accumulated in the device, and the larger is the reduction in stiffness and strength. It must be said, however, that the majority of the devices used for the seismic retrofitting

of existing structures show stable hysteretic loops for many cycles, without any appreciable degradation.

It is also worth noting here that, while FVDs and EVDs are frequency-dependent, i.e., the rate of change of displacements and forces applied to such devices changes their dynamic response, SHDs are frequency-independent, so their performance is not affected by the energy content of the dynamic excitation. Another peculiar aspect of SHDs is that they require relatively large displacements to dissipate energy, and for this reason they are specifically used for earthquake engineering applications

(while both FVDs and EVDs can also be used for other dynamic loads, e.g., to mitigate the effects of wind forces in tall buildings).

In order to perform the dynamic analysis, the equation of motion for a SDoF oscillator equipped with SHD can then be posed in the following state-space form:

$$\dot{\mathbf{y}}(t) = \mathbf{F}(\mathbf{y}(t), t), \quad (28)$$

where $\mathbf{y}(t) = \{u(t), \dot{u}(t), z(t)\}^T$ is the array of the three state variables of the system (displacement, velocity, and hysteretic variable), and $\mathbf{F}$ collects the differential equation for each state variable:

$$\mathbf{F}(\mathbf{y}(t), t) = \left\{ \begin{array}{l} \dot{u}(t) \\ -\omega_0^2 u(t) - 2\zeta_0 \omega_0 \dot{u}(t) - \beta z(t) - \ddot{u}_g(t) \\ \frac{\kappa \omega_0^2}{\beta} \left[\dot{u}(t) - \sigma |\dot{u}(t)| |\dot{z}(t)|^{n-1} \dot{z}(t) - (1 - \sigma) \dot{u}(t) |\dot{z}(t)|^n \right] \end{array} \right\}, \quad (29)$$

in which $\beta = f_y/m$ is a measure of the ground acceleration needed to reach the yielding point of the SHD and $\kappa = f_y/(k \delta_y)$ is the dimensionless stiffness of the device, normalized with respect to the elastic stiffness of the structure without damper; the superscripted T stands for the transpose operator. Different schemes of numerical integration can be used for Eqs. 28 and 29, including the 4th-order Runge–Kutta method.

As for the other types of damping mechanics considered in the previous sections, it is interesting to assess the sensitivity of their performance to the two governing parameters for SHDs, i.e., β and κ (or, alternatively, f_y and δ_y). The value of β determines the intensity of the seismic event that mobilizes the devices: if β is too small, even modest earthquakes will result in plastic deformations in the dampers; if β is too large, the dampers would only be effective for the most intense events. The selection of κ is also very important too, as it affects the fundamental period of the retrofitted structure. Indeed, if T_1 is the fundamental period of the existing structure, $T_1^* = T_1/(1 + \kappa) < T_1$ is the new period with the SHDs installed. A poor choice of κ may result in

an overall increase in the seismic forces (which would then reduce the effectiveness of the SHDs). Additionally, if κ is too small, then the existing structure would still take most of the seismic forces in the retrofitted structure, with the SHDs then being unable to dissipate enough energy during the seismic event.

Figure 14 confirms that a careful selection of the design parameters is required in order to maximize the performance of SHDs. In the top row $\beta = 1.2 \text{ m/s}^2$, which is about half of the pseudo-spectral acceleration for $T_0 = 0.5 \text{ s}$ (see Fig. 1b), and $\kappa = 1$, meaning that existing structure and retrofitting device will take the same seismic forces in the elastic range. As a result, a significant reduction in the maximum displacement is achieved (Fig. 14a), a large amount of energy is dissipated (Fig. 14d), and the ordinates of the floor spectrum are considerably mitigated (Fig. 14j). The other two rows of Fig. 14 show that lower values of yielding force ($\beta = 0.6 \text{ m/s}^2$ in the second row) and stiffness ($\kappa = 0.2$ in the third row) diminish the effectiveness of SHDs, as in both cases large displacements are then experienced by the structure.

Conclusions

In this contribution, three among the most popular passive control techniques for the seismic retrofitting of existing building structures have been reviewed. Governing equations and mathematical models have been presented for viscous fluid dampers (VFDs), elastomeric viscoelastic dampers (EVDs), and steel hysteretic dampers (SHDs), along with some examples of recent applications. A simple seismic signal, a sinusoidal function with both amplitude and frequency

varying with time, has been used to investigate the effects of the governing parameters for each type of device.

It has been shown that, despite the different damping mechanisms (viscosity of fluids, relaxation of elastomers, plasticity of metals), all these devices can significantly improve the seismic response of an existing structure, in terms of maximum displacements and floor spectra. In all cases, however, the design parameters of the added dampers must be carefully selected in order to maximize the amount of energy

time history of displacement (*first column*), hysteresis loop (*second column*), energy dissipated (*third column*) and floor spectra (*fourth column*)

dissipation, and nonlinear time-history analyses are instrumental to measure the expected benefit of the control devices.

For the sake of simplicity, all the numerical results presented have been obtained considering a single-degree-of-freedom (SDoF) oscillator. The extension of these results to multi-degree-of-freedom (MDoF) structures is straightforward if the existing building is regular both in plan and in elevation, while further

design considerations are needed to handle situations where torsional effects and soft stories are present, as larger inter-story drifts are expected at certain critical locations. Another important design constraint is the available ductility of the existing structural members. Indeed, the additional energy dissipation capacity can only be exploited if the existing structure can accommodate sufficiently large deformations.

Introduction

A seismic sensor measures the ground motion and outputs a voltage, usually proportional with ground velocity. Earlier purely mechanical sensors measured the displacement of a stylus representing the amplified ground motion while newer sensors pick up the motion using a coil moving in a magnetic field. Common for these two types of sensors is that there is no electronics involved and they are therefore called passive sensors in contrast to the many new sensors with active electric circuits as an integrated part of the sensor, the so-called active sensors.

Standard Inertia Seismometer

The objective is to measure the ground motion at a point with respect to this same point undisturbed. The main difficulty is that the measurement is done in moving reference frame. So displacement cannot be measured directly and, according to the inertia principle, an inertial force will appear on a mass only if the reference frame (in this case the ground) has an acceleration, so the seismometer can only measure velocities or displacements associated with nonzero values of ground acceleration.

Since the measurements are done in a moving reference frame (the Earth's surface), almost all seismic sensors are based on the inertia of

Passive Seismometers, Fig. 1 A mechanical inertial seismometer. *R* is a dash pot (Figure from Havskov and Alguacil 2010)

a suspended mass, which will tend to remain stationary in response to external motion. The relative motion between the suspended mass and the ground will then be a function of the ground's motion.

Figure 1 shows a simple seismometer that will detect vertical ground motion. It consists of a mass suspended from a spring. The resonance angular frequency of the mass-spring system is $\omega_0 = \sqrt{k/m}$, where $\omega_0 = 2\pi/T_0$ and T_0 is the corresponding natural period (s) of the swinging system. The motion of the mass is damped using a “dash pot” so that the mass will not swing excessively near the resonance frequency of the system. A ruler is mounted on the side to measure the motion of the mass relative to the ground.

If the ground moves with a very fast sinusoidal motion, it would be expected that the mass remains stationary and thus the ground sinusoidal motion can be measured directly as the relative mass-frame motion. The amplitude of the measurement would also be the ground's displacement amplitude and the seismometer would have a gain of 1. It is also seen that if the ground moves up impulsively, the mass moves down relative to the frame, represented by the ruler, so there is a phase shift of π (or 180°) in the measure of ground displacement. In general, a sinusoidal ground motion will produce a sinusoidal motion of the mass with the same frequency but with

a frequency-dependent phase shift and amplitude. With the ground moving very slowly, the mass would have time to follow the ground motion; in other words, there would be little relative motion, the gain would be low, and there would be less phase shift. At the resonance frequency, with a low damping, the mass could get a new push at the exact right time, so the mass would move with a larger and larger amplitude, thus the gain would be larger than 1. In order to get the exact motion of the seismometer mass relative to the ground motion including the phase shift, the equation for the swinging system must be solved.

If $u(t)$ is the ground's vertical motion and $z(t)$ the displacement of the mass relative to the ground, both positive upwards, there are two real forces acting on the mass m : the force of the deformed spring and the damping.

Spring force. $-kz$, negative since the spring opposes the mass displacement, k is the spring constant. This linear relation is strictly valid for small deformations only.

Damping force. $-d\dot{z}$, where d is the friction constant. Thus the damping force is proportional to the mass times the velocity and is negative since it also opposes the motion.

The acceleration of the mass relative to an inertial reference frame will be the sum of the acceleration $\ddot{z}$ with respect to the frame (or the ground) and the ground acceleration $\ddot{u}$.

Since the sum of forces must be equal to the mass times the acceleration, we have

$$-kz - d\dot{z} = m\ddot{z} + m\ddot{u} \quad (1)$$

For practical reasons, it is convenient to use ω_0 and the seismometer damping constant, $h = \frac{d}{2m\omega_0}$, instead of k and d , since both parameters are directly related to measurable quantities (see Havskov and Alguacil 2010). Equation 1 can then be written

$$\ddot{z} + 2h\omega_0\dot{z} + \omega_0^2 z = -\ddot{u} \quad (2)$$

This equation shows that the acceleration of the ground can be obtained by measuring the relative

displacement of the mass, z , and its time derivatives.

In the general case, there is no simple relationship between the sensor motion and the ground motion, and Eq. 2 will have to be solved so that the input and output signals can be related. This is most simply done assuming a harmonic ground motion

$$u(t) = U(\omega)e^{i\omega t} \quad (3)$$

where $U(\omega)$ is the complex amplitude and ω is the angular frequency. Equation 3 is written in complex form for simplicity of solving the equations and the real part represents the actual ground motion. Since a seismometer is assumed to represent a linear system, the seismometer mass motion is also a harmonic motion with the same frequency, and its amplitude is $Z(\omega)$

$$z(t) = Z(\omega)e^{i\omega t} \quad (4)$$

then

$$\begin{aligned} \ddot{u} &= -\omega^2 U(\omega)e^{i\omega t} \\ \dot{z} &= i\omega Z(\omega)e^{i\omega t} \\ \ddot{z} &= -\omega^2 Z(\omega)e^{i\omega t} \end{aligned} \quad (5)$$

Inserting in Eq. 2 and dividing by the common factor $e^{i\omega t}$, the relationship between the output and input complex amplitudes can be calculated as $T(\omega) = Z(\omega)/U(\omega)$, the so-called displacement frequency response function or transfer function:

$$T_d(\omega) = \frac{Z(\omega)}{U(\omega)} = \frac{\omega^2}{\omega_0^2 - \omega^2 + 2i\omega\omega_0 h} \quad (6)$$

From this expression, the amplitude displacement response $A_d(\omega)$ and phase response $\Phi_d(\omega)$ can be calculated as the modulus and phase of the complex amplitude response:

$$A_d(\omega) = |T_d(\omega)| = \frac{\omega^2}{\sqrt{(\omega_0^2 - \omega^2)^2 + 4h^2\omega^2\omega_0^2}} \quad (7)$$

$$\Phi_d(\omega) = a \tan \left(\frac{\text{Im}(T_d(\omega))}{\text{Re}(T_d(\omega))} \right) = a \tan \left(\frac{-2h\omega\omega_0}{\omega_0^2 - \omega^2} \right) \quad (8)$$

and $T_d(\omega)$ can be written in polar form as

$$T_d(\omega) = A_d(\omega)e^{i\Phi_d(\omega)} \quad (9)$$

From Eq. 7, it can be seen what happens in the extreme cases. For high frequencies

$$A_d(\omega) \rightarrow 1 \quad (10)$$

This is a constant gain of one and the sensor behaves as a pure displacement sensor.

For low frequencies,

$$A_d(\omega) \rightarrow \frac{\omega^2}{\omega_0^2} \quad (11)$$

which is proportional to acceleration and the output from the sensor is proportional to acceleration. For a high damping,

$$A_d(\omega) \approx \frac{\omega}{2h\omega_0} \quad (12)$$

and the output is proportional to ground velocity; however, the gain is low since h is high.

Figure 2 shows the amplitude and phase response of a sensor with a natural period of 1 s and damping from 0.1 to 4. As it can be seen, a low damping ($h < 1$) results in a peak in the response function. If $h = 1$, the seismometer mass will return to its rest position in the least possible time without overshooting, and the seismometer is said to be critically damped. From the shape of the curve and Eq. 7, it is seen that the seismometer can be considered a second-order high-pass filter for ground displacement. Seismometers perform optimally at damping close to critical. The most common value to use is $h = 1/\sqrt{2} = 0.707$. Why exactly this value and not 0.6 or 0.8? In practice it does not make much difference, but the value 0.707 is a convenient value to use when describing the amplitude response function. Inserting $h = 0.707$ in Eq. 7, the value for $A_d(\omega_0) = 0.707$. This is the amplitude value

used to define the corner frequency of a filter or the -3 dB point. So using $h = 0.707$ means that the response can be described as a second-order high-pass Butterworth filter with a corner frequency of ω_0 . This filter has the flattest possible response in its passband.

When the damping increases above 1, the sensitivity decreases, as described in Eq. 7, and the response approaches that of a velocity sensor (mass motion is proportional to ground velocity). From Fig. 2, it can be seen that for $h = 4$, the response approaches a straight line indicating a pure velocity response within a limited frequency band.

The Velocity Transducer

Nearly all traditional seismometers use a velocity transducer to measure the motion of the mass (example in Fig. 3). The principle is to have a moving coil within a magnetic field. This can be implemented by having a fixed coil and a magnet that moves with the mass or a fixed magnet and the coil moving with the mass. The output from the coil is proportional to the velocity of the mass relative to the frame, and this kind of electromagnetic seismometer is therefore called a velocity transducer. Two new constants are brought into the system:

Generator constant G . This constant relates the velocity of the mass to the output of the coil. It has a unit of V/ms^{-1} . Typical values are in the range of 30–500 V/ms^{-1} .

Generator coil resistance R_g . The resistance of the generator coil (also called signal coil) in Ohms (the coil is built as hundreds or thousands of turns of thin wire winding).

The signal coil makes it possible to damp the seismometer in a very simple way by loading the signal coil with a resistor. When a current is generated by the signal coil, it will oppose to the mass motion with a proportional magnetic force (see next section).

The frequency response function for the velocity transducer is different than for the mechanical sensor. With the velocity transducer, the observed output signal is now a voltage proportional to the mass-frame velocity $\dot{Z}(\omega) = i\omega Z(\omega)$ and G ,

Passive Seismometers,

Fig. 2 The amplitude and phase response functions for a seismometer with a natural frequency of 1 Hz. Curves for various levels of damping h are shown. Note that the phase shift goes toward 0 at low frequencies and toward 180° at high frequencies as qualitatively deduced

instead of $Z(\omega)$. The displacement response for the velocity sensor is then

$$\begin{aligned} T_d^v(\omega) &= \frac{\dot{Z}(\omega)}{U(\omega)} G = \frac{i\omega\omega^2 G}{\omega_0^2 - \omega^2 + i2\omega\omega_0 h} \\ &= \frac{i\omega^3 G}{\omega_0^2 - \omega^2 + i2\omega\omega_0 h} \end{aligned} \quad (13)$$

and it is seen that the only difference compared to the mechanical sensor is the factors G and $i\omega$.

For the response curve Eq. 13, the unit is $(\text{ms}^{-1}/\text{m})$ $(\text{V}/\text{ms}^{-1}) = \text{V}/\text{m}$. It is assumed in Eq. 13 that a positive velocity gives a positive voltage. Most often the response for the velocity transducer is shown for input velocity, which is Eq. 13 divided by $i\omega$:

$$T_v^v(\omega) = \frac{G\omega^2}{\omega_0^2 - \omega^2 + i2\omega\omega_0 h} \quad (14)$$

and the response looks like the displacement response for a mechanical sensor (Fig. 2). It is

Passive Seismometers,

Fig. 3 A model of an electromagnetic sensor. The coil resistance is R_g , the damping resistor is R , and the voltage output is V_{out} . The dashpot damping has been replaced by the damping from the coil moving in the magnetic field (Figure from Havskov and Alguacil 2010)

**Passive Seismometers,**

Fig. 4 Recording of a small earthquake from a 1 Hz passive sensor. The first signal recorded is the primary wave (P) and the second is the shear wave (S)

seen that the response to ground velocity is constant for $\omega > \omega_0$ and the sensor is therefore often called a velocity sensor.

In practice, the sensor output is always connected to an external resistor R_e (for damping control and because amplifiers have a finite input impedance). This forms a voltage divider. Thus the effective generator constant (or loaded generator constant) G_e becomes

$$G_e = G \cdot \frac{R_e}{R_e + R_g} \quad (15)$$

and this must be used in Eqs. 13 and 14 instead of G . All available passive seismometers are now using a velocity transducer and the most common way to use the is to digitize it and record it in a computer. The signal can then be plotted to show the so-called seismogram, an example in Fig. 4.

Other passive sensors, seldom used for earthquake recording, but quite common in structural dynamics monitoring, are piezoelectric accelerometers. An inertial mass is fixed on a piezoelectric material (normally in a multilayer arrangement), which has an elastic behavior. Due to the high elastic compliance, the resulting natural frequency of the system is also high and the strain is proportional to ground acceleration up to this frequency. Because of piezoelectricity, the system output is an electric charge proportional to the strain, so a charge amplifier (current integrator) is used to yield a voltage proportional to acceleration. In practice, the charge amplifier cannot perform a perfect integration up to DC ($\omega = 0$), so there is some low-frequency limit for the flat response to acceleration.

The piezoelectric properties of some materials are quite temperature dependent and this has to be somehow compensated for.

Damping

For a purely mechanical seismometer there is a damping h_m due to friction (mainly air friction and spring internal elastic dissipation) of the mechanical motion. In a sensor with electromagnetic transducer, a voltage E is induced in the coil proportional to velocity. If the signal coil is shunted with an external resistance, let R_T be the total circuit resistance, then a current $I = E/R_T$ (neglecting self-induction) will flow through the circuit. This will cause a force on the mass proportional to this current and in the sense opposed to its motion, as is given by Lenz law. This will introduce an additional electrical or electromagnetic damping h_e .

Thus the total damping is the sum of electromagnetic and mechanical contributions:

$$h = h_e + h_m \quad (16)$$

h_m is also called open-circuit damping, since this is the damping of the seismometer with no electrical connection. The mechanical damping, hereafter called open-circuit damping, cannot be changed and range from a very low value of 0.01 to 0.3 while the electrical damping can be regulated with the value of the external resistor to obtain a desired total damping. The electrical damping can be calculated as (Havskov and Alguacil 2010)

$$h_e = \frac{G^2}{2M\omega_0 R_T} \quad (17)$$

where M is the seismometer mass and R_T is the total resistance of the generator coil and the external damping resistor. Seismometer specifications often give the critical damping resistance CDR , which is the total resistance $CDR = R_T$ required to get a damping of 1.0.

From Eqs. 17 and 16, it is seen that if the total damping h_1 is known for one value of R_T , R_{T1} , the required resistance R_{T2} for another required total damping h_2 can be calculated as

$$R_{T2} = R_{T1} \frac{h_1 - h_m}{h_2 - h_m} \quad (18)$$

If the mechanical damping is low ($h_m \approx 0$), Eq. 18 can be written in terms of CDR ($h_2 = 1$, $CDR = R_{T1}$) as

$$R_{T2} = \frac{CDR}{h_2} \quad (19)$$

and thus, the desired total resistance for any required damping can easily be calculated from CDR .

As an example, consider the classical 1 Hz sensor, the Geotech S13 (Fig. 15). The coil resistance is 3,600 Ω and $CDR = 6,300 \Omega$. Since the open-circuit damping is low, it can be ignored. The total resistance to get a damping of 0.7 would then, from Eq. 19, be $R = 6,300/0.7 = 9,000 \Omega$, and the external damping resistor to connect would have a value of $9,000 - 3,600 = 5,400 \Omega$.

Construction of Passive Sensors

The mass-spring system of the vertical seismometer serves as a very useful model for understanding the basics of seismometry. However, in practical design, this system is too simple, since the mass can move in all directions as well as rotate. So, nearly all seismometers have some mechanical device which will restrict the motion to one translational axis. Figure 5 shows how this can be done in principle for a vertical seismometer.

It can be seen that due to the hinged mass, the sensor is restricted to move vertically. The mass does not only move in the z direction but in a circular motion with the tangent to the vertical direction. However, for small displacements, the motion is sufficiently linear. The above pendulum arrangement is in principle the most common way to restrict motion and can also be used for horizontal seismometers. Pendulums are also sensitive to angular motion in seismic waves, which normally is so small that it has no practical importance.

Passive Seismometers, Fig. 5 A vertical mass-spring seismometer where the horizontal motion has been restricted by a horizontal hinged rod. Usually, the hinge

is a thin flexible leaf to avoid friction (Figure from Havskov and Alguacil 2010)

Passive Seismometers, Fig. 6 Horizontal seismometer made with a pendulum (From <http://www.azosensors.com/>)

So far only a vertical seismometer has been described; however, the ground motion must be measured in all three directions, x , y , and z . Normally z is positive up, x is to the east, and y to the north. A horizontal seismometer is in its simplest form a pendulum (see Fig. 6).

For a small-size mass m compared to the length L of the string, the natural frequency

$$\omega_0 = \sqrt{g/L} \quad (20)$$

where g is the gravitational constant. For small translational ground motions, the equation of motion is identical to Eq. 1 with z replaced with the angle of rotation. Note that ω_0 is independent of the mass.

It is relatively easy to make sensors with a natural frequency down to 1 Hz (so-called short-period (SP) seismometers), but in seismology it is desirable to measure much lower frequencies using so-called long-period (LP)

Passive Seismometers, Fig. 7 Principle of the garden-gate pendulum. The tilt angle is exaggerated. A string pendulum must have length L to have the same period, so at a small angle α , L becomes very large (Figure from Havskov and Alguacil 2010)

seismometers, and a good station with a passive sensor should be able to measure down to ideally 0.01 Hz. For the vertical seismometer, this would require a very soft spring combined with a heavy mass, which is not possible in practice. For the pendulum, L would have to be very long. For a 1 Hz seismometer, it would be 9.8 m. So there are various ways of making the natural frequency smaller without using a very large design; however, in practice it is hard to achieve less than 0.03 Hz with a passive seismometer, while active seismometers can go down to 0.003 Hz.

For a horizontal seismometer, the simplest solution is the “garden-gate” pendulum (Fig. 7). The mass moves in a nearly horizontal plane around a nearly vertical axis. The restoring force is now $g \sin(\alpha)$ where α is the angle between the vertical and the rotation axis, so the natural frequency becomes

$$\omega_0 = \sqrt{g \sin(\alpha)/L} \quad (21)$$

where L is the vertical distance from the mass to the point where the rotation axis intersects the vertical above the mass (see Fig. 7).

To obtain a natural frequency of 0.05 Hz with a pendulum length of 20 cm will require a tilt of 0.1° . This is close to the lowest stable period that has been obtained in practice with these instruments. Making the angle smaller makes the instrument very sensitive to small tilt changes. The “garden gate” was one of the earliest designs for long-period horizontal seismometers. It is still in use in a few places but no longer produced. Until the new broadband sensors were installed in the GSN (Global Seismographic Network), this kind of sensors was used in the WWSSN (World-Wide Standardized Seismograph Network) (see, e.g., Peterson and Orsini 1976).

The *astatic* spring geometry for vertical seismometers was invented by LaCoste (1934). The principle of the sensor is shown in Fig. 8. The sensor uses a “zero-length spring” which is designed such that the force $F = k \cdot L$, where L is the *total* length of the spring. Normal springs used in seismometers do not behave as zero-length springs, since $F = k \cdot \Delta L$, where ΔL is the change in length relative to the unstressed length of the spring. However, it is possible to construct a “zero-length spring” by, e.g., twisting the wire as it is wound into a spring. The physical setup is to have a mass on a beam and supported by the spring so that the mass is free to pivot around the lower left hand point.

This system can be constructed to have an infinite free period, which means that the vertical restoring force must cancel the gravity force at any mass position. Therefore, if the mass is at equilibrium at one angle, it will also be at equilibrium at another angle, which is similar to what was obtained for the garden-gate horizontal seismometer. Qualitatively, what happens is that if, e.g., the mass moves up, the spring force lessens, but it turns out the force from gravity in direction of mass motion is reduced by the exact same amount, due to the change in angle as will be shown below.

Passive Seismometers,

Fig. 8 The principle behind the LaCoste suspension. The mass m is sitting on a hinge, which has an angle α with the horizontal and suspended by a spring of length L (Figure from Havskov and Alguacil 2010)

The gravity force F_g acting on the mass in direction of rotation can be written as

$$F_g = mg \cos(\alpha) \quad (22)$$

while the spring restoring force F_s acting in the opposite sense is

$$F_s = kL \cos(\lambda) \quad (23)$$

λ can be replaced by α using the law of sines:

$$\begin{aligned} \frac{L}{\sin(90 - \alpha)} &= \frac{y}{\sin(90 - \lambda)} \text{ or } \cos(\lambda) \\ &= \frac{y}{L} \cos(\alpha) \end{aligned} \quad (24)$$

Equating F_s and F_g and including the expression for $\cos(\lambda)$ gives

$$ky = mg \text{ or } y = mg/k \quad (25)$$

As long as this condition holds, the total force is zero independent of the angle. As with the garden-

gate seismometer, this will not work in practice and, by inclining the vertical axis slightly, any desired period within mechanical stabilization limits can be achieved. In practice, it is difficult to use free periods larger than 20–30 s.

The astatic leaf-spring suspension (Wielandt and Streckeisen 1982) is comparable to the LaCoste suspension, but simpler to make (Fig. 9). The delicate equilibrium of forces in astatic suspensions makes them sensitive to external disturbances, so they are difficult to operate without a stabilizing feedback system.

The LaCoste pendulums can be made to operate as vertical seismometers, as has been the main goal or as sensors with an oblique axis. Sensors with an oblique axis are used to obtain both vertical and horizontal motions. The normal arrangement for a 3-component sensor is to have 3 sensors oriented in the Z , N , and E directions. Since horizontal and vertical seismometers differ in their construction, it is difficult to make them equal. A three-component sensor can be constructed by using three identical sensors whose axes U , V , and W are inclined against the vertical like the edge of

Passive Seismometers, Fig. 9 Leaf-spring astatic suspensions. The figure to the *left* shows a vertical seismometer and to the *right* an oblique axis seismometer (Figure from <http://jclahr.com/science/psn/wielandt/node15.html>)

Passive Seismometers, Fig. 10 The triaxial geometry of the STS-2 seismometer. The oblique components are *W*, *V*, and *U* (Figure from Havskov and Alguacil 2010)

a cube standing on its corner (Fig. 10). Each sensor is made with an *astatic* leaf-spring suspension (Fig. 9). The angle of inclination is $\tan^{-1}\sqrt{2} = 54.7$ degrees, which makes it possible to electronically recombine the oblique components to *X*, *Y*, and *Z* simply

$$\begin{pmatrix} X \\ Y \\ Z \end{pmatrix} = \frac{1}{\sqrt{6}} \cdot \begin{pmatrix} -2 & 1 & 1 \\ 0 & \sqrt{3} & -\sqrt{3} \\ \sqrt{2} & \sqrt{2} & \sqrt{2} \end{pmatrix} \begin{pmatrix} U \\ V \\ W \end{pmatrix} \tag{26}$$

This arrangement is now the heart of some modern active seismic sensors with a natural

frequency below 0.1 Hz. Figure 11 shows an example of a long-period recording.

For more details on passive seismic sensors, see also the New Manual of Seismological Observatory Practice (NMSOP-2), Bormann (2012), Aki and Richards (1980), and the old Manual of Seismological Observatory Practice, Wilmore (1979).

Sensitivity of Passive Sensors

The output from a passive sensor V_{out} is, above its natural frequency,

Passive Seismometers, Fig. 11 Example of recording an earthquake using a long-period sensor. Note the low frequency of the signal. The distance from the location of

the earthquake (epicenter) to the recording station is 3,500 km. The harmonic waves at the end of the record are surface waves traveling along the Earth’s surface

$$V_{\text{out}} = GV \tag{27}$$

where V is the ground velocity. At a low-noise site, the ground velocity amplitude is typically 10 nm/s and a typical value of the generator constant is 100 V/ms⁻¹ so the output would be 1 μV. This is the ground seismic signal. The sensor itself will, since it has no active electronics, usually produce less than 10 times this in electrical noise from the Brownian motion of the mass and the current flowing through the coil. So in general, passive seismic sensors can easily be made sensitive enough for most sites. The low-level output must be amplified to be recorded. For analog recording, this means a sensitive amplifier (usually with a noise level of 0.1 μV), while modern recording systems use digital recording. Many digital recorders will have a noise level also of 0.1 microvolt, meaning the number 1 (one count) corresponds to 0.1 μV and the seismic noise signal would then be recorded with 10 counts of resolution. Active sensors usually have higher electrical outputs, so not all digital recorders have enough sensitivity for passive sensors. For frequencies f below the natural frequency, the response decreases proportional to f^2 . So, for a 1 Hz sensor, the sensitivity is down by a factor of 100 at 0.1 Hz. Since the Earth’s natural background noise also increases for frequencies below 1 Hz until about 0.2 Hz (Fig. 12), a 1 Hz seismometer will in practice have sufficient sensitivity for most seismological applications down to 0.1 Hz.

Passive Seismometers, Fig. 12 Typical amplitude of the microseismic background noise as a function of period(s) (The data for the plot are taken from Brune and Oliver 1959)

Examples of Some Passive Sensors

Passive sensors are today only sold for sensors with a natural frequency at 1 Hz and higher. For sensors with a lower natural frequency, active sensors are now both smaller, better, and cheaper than the old passive sensors and therefore no longer constructed. For earthquake seismology, it is particularly sensors with natural frequencies of 1, 2 and 4.5 Hz that are used, with the 1 Hz sensor the natural choice and there are still hundreds of seismic stations with 1 Hz sensors.

Passive Seismometers,

Fig. 13 Typical construction of a geophone. Note the leaf-spring suspension. The magnet is fixed to the case and the coil moves with the mass <http://vibration.desy.de/equipment/geophones/>

**Passive Seismometers,**

Fig. 14 The Geospace GSX recorder (box below) connected to a small battery and a Geospace three-component 2 Hz geophone (green cylinder) (Figure from www.geospace.com)

P

Sensors with a frequency up to 4.5 Hz and above are constructed in the thousands and mostly used for exploration purposes and they are usually called geophones, in contrast to the 1 Hz sensor which is usually called a seismometer.

Geophone: An example is seen in Fig. 13. It is small in size (about 3×5 cm) and only costs about \$100, since it is produced in large numbers for seismic exploration. It typically has a mass of 20 g and the generator constant is often around 30 V/ms^{-1} .

The sensor is very simple and robust to use. Due to its low sensitivity, it requires more amplification than the standard sensors.

It has traditionally not been used for earthquake recording as much as the 1 Hz sensor; however, with more sensitive and higher dynamic range recorders, it is now possible to use it directly without any special filtering and obtain good recordings down to 0.3 Hz by post processing.

A modern 2 Hz, three-component geophone (Fig. 14). This is a very compact 2 Hz sensor used both for earthquake recording and seismic exploration. The figure shows how compact it is possible to make a complete seismograph.

A classical 1 Hz seismometer, the S13 from Geotech (see Fig. 15): This 1 Hz seismometer is

one of the most sensitive passive 1 Hz seismometers produced and it has been the standard by which other 1 Hz seismometers are measured. It is suspended by both leaf and helical springs

Passive Seismometers, Fig. 15 Geotech S13 seismometer (The picture is from www.bgr.bund.de/EN/Themen/Seismologie/Seismologie/Seismometer_Stationen/stationen_node.html)

Passive Seismometers, Fig. 16 The ranger 1 Hz seismometer from Kinemetrics (Figure from www.kinemetrics.com)

in such a way that by an internal adjustment, the sensor can be used both as a vertical and horizontal seismometer. It is still produced.

Another classical 1 Hz seismometer from Kinemetrics (Fig. 16). This seismometer was designed for the Moon and then later produced in a terrestrial version and is still produced. It can work both as a horizontal and vertical seismometer by an external adjustment.

A long-period horizontal seismometer (Fig. 17). This seismometer was used by the WWSSN and was thus produced in large numbers. The longest practical free period was 30 s and it was mostly used with a 25 s period. At very stable sites, periods larger than 30 s have been used.

Summary

Passive seismic sensors function without internal electronics, so no power supply is required, and they have been in operation for more than 100 years. All modern passive sensors are of the so-called velocity types, meaning that the voltage output is proportional to the ground velocity for frequencies above the sensor's natural frequency. Passive LP sensors are no longer sold. Compared to active sensors, passive SP sensors are low cost, very stable, and very sensitive but cannot easily resolve signals for frequencies below 1 Hz, although a good 1 Hz sensor can provide useful signals down to 0.1 Hz. Passive sensors (both 1 and

Passive Seismometers, Fig. 17 A typical horizontal long-period seismometer which was made by Sprengnether (no longer exists). The two *black* cylinders seen at each side are the magnets and the coils are moving inside with the mass in the *center*. Leveling is done with the three screws at the corners of the base plate. Once the horizontal leveling is done (front screws), the back screw is used to adjust the period. The base plate side length is 63 cm and the weight 45 kg

4.5 Hz) are still a good choice for recording small earthquakes, while the higher-frequency geophones are mostly used for seismic exploration.

Introduction

It is well-known that supplemental damping devices increase the energy dissipation capacity

of structures, reducing the seismic demand on the primary structure (Constantinou et al. 1998; Soong and Dargush 1997). A structural system with supplemental dampers is often represented by an equivalent linear system. Kwan and Billington (2003) derived optimal equations for the equivalent period and damping ratio of SDOF systems with various nonlinear hysteresis loops based on time-history analysis and regression analysis. Symans and Constantinou (1998) studied the dynamic behavior of SDOF systems with linear or nonlinear viscous fluid dampers and derived an equation for the equivalent damping ratio of the nonlinear viscous fluid damper. Ramirez et al. (2002) proposed a simplified method to estimate displacement, velocity, and acceleration for yielding structures with linear or nonlinear viscous dampers. Lin and Chopra (2003) investigated the behavior of SDOF systems with a diagonal brace in series with a nonlinear viscous damper by transforming the system to an equivalent linear Kelvin model.

Fan (1998) investigated the behavior of nonductile reinforced concrete frame buildings with viscoelastic dampers. He derived an equivalent elastic-viscous model based on the complex stiffness and energy dissipation of the viscoelastic system and proposed a simplified design procedure for a structure with viscoelastic dampers. Lee et al. (2005, 2009) applied this method to structures with elastomeric dampers and validated the simplified design procedure by comparing the design demand with the results from nonlinear time-history analysis.

In this paper, a systematic procedure for the design of structures with MR dampers, referred to as the *Simplified Design Procedure* (SDP), is developed. The procedure is similar to that developed by Lee et al. (2005, 2009), but with modifications to account for the characteristics of the MR dampers. A quasistatic MR damper model for determining the loss factor and the effective stiffness of an MR damper is introduced and incorporated into the procedure to calculate the design demand for the structure with MR dampers. The procedure is evaluated by comparing the predicted design demand to the seismic

response determined from nonlinear time-history analysis.

Simplified Design Procedure (SDP)

In the SDP developed by Lee et al. (2005, 2009), the supplemental damper properties are represented by β , which is the ratio of the damper stiffness per story in the global direction to the lateral load resisting frame story stiffness, k_0 , without dampers and braces of the structural system. The structural system with dampers is converted into a linear elastic system characterized by the initial stiffness of the structure, α (the ratio of brace stiffness per story in the global direction to the lateral load resisting frame story stiffness k_0), β , and η . α , β , and η may vary among the stories of the structure. By conducting an elastic-static analysis with the RSA method, the design demand for the structure is determined.

Since the loss factor of an MR damper depends on the displacement of the structure, as can be shown below in Eq. 8, the SDP for an elastomeric damper developed by Lee et al. (2005, 2009) needs to be modified for structures with MR dampers. The loss factor η is associated with the energy dissipation of the damper over a cycle. For the purpose of determining the energy dissipation over a cycle of displacement, the properties of the MR damper are assumed to remain constant. The linearization and energy dissipation of an MR damper are discussed later.

Figure 1 summarizes the SDP for structures with MR dampers. In Step 1, the seismic performance objectives and associated design criteria are established for the design of the structure. In Step 2, the structure is designed without MR dampers in accordance with the design code selected in Step 1 to satisfy the strength requirement for the members in the structure. In Step 3, the MR dampers are incorporated into the design of the structure to satisfy the specified performance objectives. The design demand for the structure is estimated for a range of selected values for α , β , and a constant loss factor $\eta = 4/\pi$

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers,

Fig. 1 Generalized simplified design procedure (SDP) for structures with MR dampers

using a *simplified analysis procedure*, discussed later. In the simplified analysis procedure, the MR damper behavior is based on the simple frictional MR damper model (Chae 2011). The required MR damper sizes are then selected in Step 4 based on the smallest β value that meets the design criteria and performance objectives in Step 1. Since the simple frictional damper model does not account for the velocity dependent behavior of an MR damper, a more accurate determination of the design demand is determined in Step 5 using a more sophisticated MR damper model (i.e., Hershel-Bulkley model) in the simplified analysis procedure. The design is then revised with final member sizes and the MR

damper sizes are selected (location, number, force capacity, etc.). If the performance objectives cannot be met in an economical manner, then the performance objectives and/or structural system design need to be revised as indicated in Fig. 1.

Equivalent Linear System for an MR Damper

The SDP requires that the structure with the nonlinear MR dampers be linearized. In order to linearize the system for estimating the response of structures with MR dampers, the

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers, Fig. 2 Hershel-Bulkley visco-plasticity MR damper model: (a) force-velocity relationship; (b) force-displacement relationship

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers, Fig. 3 SDOF system: (a) schematic of equivalent SDOF system with MR damper and brace; (b) mechanical model

Hershel-Bulkley quasi-static MR damper model is used. Figure 2 shows the force-velocity and force-displacement relationships for the model where the damper force f is given as

$$f = \text{sign}(\dot{u})\{f_0 + C|\dot{u}|^n\} \quad (1)$$

In Eq. 1 u is the damper displacement relative to the initial position of the damper and $\dot{u}$ is the damper velocity. f_0 is the frictional force. C and n are the coefficients of the nonlinear dashpot. Suppose that the MR damper is subjected to a harmonic displacement motion

$$u(t) = u_0 \sin(\omega t) \quad (2)$$

where u_0 is the amplitude of displacement and ω is the excitation frequency of the damper. The energy dissipated by the damper over one cycle of the harmonic motion is equal to

$$E_{MRD} = \int_0^{2\pi/\omega} f(t)\dot{u}(t)dt = 4f_0u_0 + 2^{n+2}C\gamma(n)u_0^{1+n}\omega^n \quad (3)$$

where

$$\gamma(n) = \frac{\Gamma^2\left(1 + \frac{n}{2}\right)}{\Gamma(2 + n)} \quad (4)$$

In Eq. 4, $\Gamma()$ is the gamma function (Soong and Dargush 1997). In general, diagonal bracing is installed in the building in series with the dampers. Therefore, the energy dissipation of an MR damper needs to be studied considering the stiffness of the diagonal bracing. Figure 3 shows an SDOF system with an MR damper and diagonal bracing. Under the harmonic motion $x = x_0 \sin(\omega t)$, the maximum damper displacement, u_{d0} , and velocity, $\dot{u}_{d0}$, of the MR damper occurs when the displacement x and velocity $\dot{x}$ are a maximum, respectively, where u_{d0} and $\dot{u}_{d0}$ can be calculated as (Chae 2011)

$$u_{d0} = x_0 - f_0/k_{br} \quad (5a)$$

$$\dot{u}_{d0} = \dot{x}_0 = x_0\omega \quad (5b)$$

In Eq. 5a k_{br} is the stiffness of the diagonal bracing. Substitution of Eq. 5a into Eq. 3 results

in the expression for the energy dissipation of the MR damper for a SDOF system

$$E_{MRD} = 4f_0 u_{d0} + 2^{n+2} C \gamma(n) u_{d0}^{n+1} \omega^n \quad (6)$$

The strain energy of the MR damper, E_S , is calculated from the equivalent stiffness of the damper and the maximum damper displacement:

$$E_S = \frac{1}{2} k_{eq} u_{d0}^2 \quad (7)$$

where k_{eq} is the equivalent stiffness of the MR damper, defined as $k_{eq} = f_0 / u_{d0}$ and based on the secant stiffness from the force-displacement relationship of the Hershel-Bulkley model. The loss factor η of the MR damper by definition is

$$\eta = \frac{1}{2\pi} \frac{E_{MRD}}{E_S} = \frac{4\{f_0 + C\gamma(n)(2u_{d0}\omega)^n\}}{\pi k_{eq} u_{d0}} \quad (8)$$

Simplified Analysis Procedure

The simplified analysis procedure provides an elastic-static method for calculation of the design demand of an MDOF system with MR dampers. The simplified analysis procedure utilizing the response spectrum analysis (RSA) method is summarized in Figs. 4 and 5.

In the simplified analysis procedure, the maximum structural displacements are determined by the well-known equal displacement rule. In the equal displacement rule, the maximum displacement of the nonlinear structure, whose lateral stiffness is based on its initial tangent stiffness, is assumed to be equal to that of a linear structure. The equal displacement rule is only applicable to structures that lie in the low-frequency and medium-frequency spectral regions (Newmark and Hall 1973).

In order to obtain the equivalent period for an MDOF structure with MR dampers, the combined stiffness of the MR dampers and diagonal

bracing needs to be added to the stiffness of the structure. Thus, the global effective stiffness of the MDOF system is given as

$$\mathbf{K}_{\text{eff}} = \mathbf{K}_0 + \mathbf{K}_{\text{brsystem}} \quad (9)$$

where $\mathbf{K}_0$ is the stiffness of the structure without diagonal braces and MR dampers, and $\mathbf{K}_{\text{brsystem}}$ is the stiffness associated with the braces and MR dampers. The structure is assumed to have N DOF, thus the dimension of $\mathbf{K}_{\text{eff}}$ is $N \times N$. The combined stiffness K_{brsystem}^i of the diagonal bracing and MR damper at the i -th MR damper location is

$$K_{\text{brsystem}}^i = \frac{k_{br}^i k_{eq}^i}{k_{br}^i + k_{eq}^i} \quad (10)$$

where k_{br}^i and k_{eq}^i are the horizontal stiffness of the diagonal bracing and the MR damper associated with the i th MR damper, respectively. k_{eq}^i can be calculated utilizing the secant stiffness method as noted above. The individual combined stiffnesses based on Eq. 10 are appropriately assembled to form $\mathbf{K}_{\text{brsystem}}$. The effective periods and mode shapes of the structure are then obtained by performing an eigenvalue analysis of the structure, considering the seismic mass of the structure.

The equivalent damping ratio ξ_{eq} of an MDOF system is determined using the lateral force energy method proposed by Sause et al. (1994), where

$$\xi_{eq} = \frac{1}{2} \frac{\sum_{i=1}^L \eta_i F_d^i u_d^i}{\mathbf{F}^T \mathbf{x}_0} + \xi_{in} \quad (11)$$

In Eq. 11 η_i and u_d^i are the loss factor and maximum damper displacement of the i th MR damper, respectively, and L is the number of MR dampers. Since the damper displacement is unique for each MR damper, the loss factor of each MR damper, which is a function of damper displacement, is also unique for each damper. For each damper η_i is obtained from Eq. 8. ξ_{in} in

Given:

- MR damper properties: f_0^i , C_i , n_i (i : index for MR damper location)
- Structural properties: $\mathbf{M}$, $\mathbf{K}_0$, k_{br}^i , ξ_{in}^j (inherent damping ratio of the j -th mode)

Step 1. Assume $\mathbf{x}_0$ and set $\omega_{eff}^1 = \omega_n^1$ (fundamental frequency of structure without MR dampers)

Step 2. Determine maximum damper displacements

$$u_{d0}^i = u_0^i - f_0^i / k_{br}^i$$

u_0^i : maximum deformation of damper and bracing of the i^{th} MR damper

Step 3. Calculate equivalent stiffness of each MR damper

$$k_{eq}^i = f_0^i / u_{d0}^i$$

Step 4. Determine $K_{brsystem}^i = \frac{k_{br}^i k_{eq}^i}{k_{br}^i + k_{eq}^i}$ for each MR damper and update $\mathbf{K}_{eff}$

Step 5. Update modal frequency ω_{eff}^j and modal vector ϕ_j ($j = 1, \dots, N$)

$$\omega_{eff}^j, \phi_j \leftarrow \text{eig}(\mathbf{K}_{eff}, \mathbf{M})$$

where $\mathbf{M}$ is the mass matrix of the structure

Step 6. Calculate loss factor of each MR damper

$$\eta_i = \frac{4\{f_0^i + C_i \gamma(n_i)(2u_{d0}^i \omega_{eff}^1)^{n_i}\}}{\pi k_{eq}^i u_{d0}^i}$$

where ω_{eff}^1 is the fundamental modal frequency

Step 7. Perform modal analysis described in Figure 5

Step 8. Apply the modal combination rule (e.g., SRSS or CQC) to get the final displacement $\mathbf{x}_0$ and velocity of each MR damper $\dot{u}_{d0}^i$

$$\mathbf{x}_0 = \text{function of } (\mathbf{x}_0^1, \dots, \mathbf{x}_0^N),$$

$$\dot{u}_{d0}^i = \text{function of } (\dot{u}_{d0}^{i1}, \dots, \dot{u}_{d0}^{iN})$$

Step 9. Repeat **Step 2** ~ **Step 8** until $\mathbf{x}_0$ convergence is achieved.

Step 10. Calculate maximum damper force for each MR damper

$$f_{max}^i = f_0 + C(\dot{u}_{d0}^i)^n$$

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers,
Fig. 4 Simplified analysis procedure used to design

MDOF structures with passive MR dampers utilizing response spectrum analysis (RSA) method

Eq. 11 is the inherent damping ratio and $\mathbf{x}_0$ is the vector of the displacements of the structure that develop under the lateral force $\mathbf{F}$. The individual damper force F_d^i and the lateral force vector $\mathbf{F}$ are defined as

$$F_d^i = k_{eq}^i u_d^i, \quad \mathbf{F} = \mathbf{K}_{eff} \mathbf{x}_0 \quad (12)$$

In the simplified analysis procedure using the RSA, the relationships in Eq. 12 are substituted into Eq. 11, and the inherent damping ξ_{in} and $\mathbf{x}_0$

from each mode are considered, as indicated in Substep 3 in Fig. 5.

Performance-Based Design of a Three-Story Building with MR Dampers

Prototype Building Structure

Based on the proposed SDP, a three-story building with MR dampers is designed. The floor plan and elevation of the prototype structure is shown

Step 7. For $j=1$ to N^{th} mode

Substep 1. Assume modal displacement vector $\mathbf{x}_0^j$

Substep 2. Determine maximum displacement for each damper u_{d0}^{ij}

$$u_{d0}^{ij} = u_0^{ij} - f_0^i / k_{br}^i$$

u_0^{ij} : maximum deformation of damper and bracing at the i^{th} MR damper in mode j

Substep 3. Calculate equivalent modal damping ratio

$$\xi_{eq}^j = \frac{1}{2} \frac{\sum_{i=1}^L \eta_i k_{eq}^i (u_{d0}^{ij})^2}{\mathbf{x}_0^{jT} \mathbf{K}_{eff} \mathbf{x}_0^j} + \xi_{in}^j$$

Substep 4. Find maximum modal displacement (y_0^j) from response spectrum

$$y_0^j = S_d(T_{eff}^j, \xi_{eq}^j) \quad \text{where } T_{eff}^j = 2\pi / \omega_{eff}^j$$

Substep 5. Update modal displacement vector $\mathbf{x}_0^j$

$$\mathbf{x}_0^j = \Gamma_j^T \boldsymbol{\phi}_j y_0^j$$

$\boldsymbol{\phi}_j$: mode vector; $\Gamma_j = \boldsymbol{\phi}_j^T \mathbf{M} \mathbf{1} / M_j$; $\mathbf{1}$: unit vector; M_j : modal mass ($= \boldsymbol{\phi}_j^T \mathbf{M} \boldsymbol{\phi}_j$)

Substep 6. Repeat Substep 2 ~ 5 until convergence in $\mathbf{x}_0^j$ is achieved

Substep 7. Calculate maximum velocity $\dot{u}_{d0}^{ij}$ for each MR damper, where for the i^{th} MR damper

$$\dot{u}_{d0}^{ij} = u_0^{ij} \omega_{eff}^j$$

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers, Fig. 5 Modal analysis method for the simplified analysis procedure utilizing response spectrum analysis (RSA) method

in Figs. 6 and 7, respectively. It consists of a three-story, six-bay building and represents a typical office building located in Southern California. Lateral loads are resisted by a four perimeter moment resisting frames (MRFs) and four damped braced frames (DBFs) in the two orthogonal principle directions of the building's floor plan. MR dampers are installed in the DBFs to control the drift of the building, adding supplemental damping to the structure. The DBFs have continuous columns, with pin connections at the beam-to-column connections and at the ends of the diagonal bracing. A rigid diaphragm system is assumed to exist at each floor level and the roof of the building to transfer the floor inertia loads to the MRFs and DBFs. The building has a base-moment where a point of inflection is assigned at one third of the height of the column from the column base in the analysis model.

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers, Fig. 6 Floor plan of prototype building

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers,

Fig. 7 Elevation of prototype building

Performance Objectives

In this design, three different performance objectives for the building are considered:

1. Limit the story drift to 1.5 % under the DBE ground motion
2. Limit the story drift to 3.0 % under the MCE ground motion
3. Design strength of members in the DBF shall not be exceeded by the demand imposed by the DBE ground motion

The MCE ground motion is represented by a response spectra that has a 2 % probability of exceedance in 50 years, and the DBE ground motion is two third the intensity of the MCE ground motion (FEMA 2000a). The performance objectives of 1.5 % story drift satisfies the life safety performance level under the DBE, and the 3 % story drift satisfies the collapse prevention level under the MCE. The performance levels are defined in FEMA-356 (2000b). To minimize the damage and repair cost to the DBF structure, the third performance objective is adopted to have the DBF structure remain elastic under the DBE.

Performance-Based Design

The prototype building structure is intended to provide the basis for an MRF and DBF with MR dampers which can be constructed in the laboratory for future tests. Due to laboratory constraints, the prototype building structure and resulting MRF and DBF were designed at 0.6-scale. The MRFs are designed to satisfy the

strength requirement of the current building seismic code of ICC (2006); the member design criteria is based on the AISC steel design provisions (2005b). The design response spectrum is based on a site in Southern California where the spectral acceleration for the short period, S_s , and for a 1 s period, S_1 , are equal to 1.5 and 0.6, respectively. The strength contribution from the DBFs and MR dampers is not considered when the MRFs are designed since, as noted above, the DBFs and MR dampers are intended only to control the story drift of the building system. More detailed information on the design of the MRFs and gravity frames can be found in Chae (2011).

Once the MRFs and gravity frames are designed for strength, the required capacity of the MR dampers to control the drift is determined. The DBF members are then designed by imposing the displacement and damper force demands on the DBF, which are obtained from the simplified analysis procedure and the required MR damper capacity. The maximum displacements and the maximum MR damper forces are assumed to occur concurrently in the SDP. The design of the three-story building is revised until the performance objectives and strength requirements are satisfied.

Large-scale MR dampers were used for the study which can generate a 200 kN damper force at a velocity of 0.1 m/s (Chae et al. 2010). The parameters for the Hershel-Bulkley model associated with the large-scale MR damper are: $f_0 = 138.5$ kN, $C = 161.8$ kNsec/m, and $n = 0.46$.

The optimal damper location which satisfies the performance objectives is determined by using the simplified analysis procedure, resulting in one large-scale MR damper in the second and third stories, respectively, with $\alpha = 10$ and $\beta = 0.3$ (Chae 2011). Tables 1 and 2 summarize the member sizes for the MRFs, gravity frames, and DBFs. Table 3 summarizes the calculated design demand associated with maximum story drift and maximum damper forces. As can be observed, the design demand for the story drift under the DBE and MCE are less than 1.5 % and 3.0 %, respectively, in order to satisfy the performance objectives. Table 4 shows the DBE demand-to-capacity ratios for the DBF members. The demand-to-capacity ratio for each member is less than 1.0, which means the members

are designed to remain elastic under the DBE. The design of the braces was controlled by stiffness, $\alpha = 10$, and not strength, hence, the demand-to-capacity ratios for the braces are small in Table 4.

Assessment of Simplified Design Procedure

The SDP is assessed by comparing the design demand from the SDP with results from a series of nonlinear time-history analyses (NTHA) of the three-story building using the nonlinear finite element program OpenSees (2009).

OpenSees Model

Symmetry in the floor plan and ground motions along only one principal axis of the building were considered in the analysis. Hence, only one-quarter of the building was modeled consisting of one MRF, one DBF, and the gravity frames that are within the tributary area of the MRF and DBF. The OpenSees model is shown in Fig. 8. The beams and columns of the MRF structure are modeled with a nonlinear distributed plasticity force-based beam-column element with five fiber sections along the element length. The cross section of the element is discretized into 18 fibers, including 12 fibers for the web and 3 fibers each for the top and bottom flanges. Each fiber is modeled with a bilinear stress-strain relationship with a post-yielding stiffness that is 0.01 times the elastic stiffness. The beam-column joints in the MRF are modeled using a panel zone element, where shear and symmetric column bending deformations are considered (Seo et al. 2009). The doubler plates in the panel zones of the MRF are included in the model.

The nonlinear force-based fiber element is also used to model the columns of the DBF. The beams and braces of the DBF are modeled using linear elastic truss elements. The gravity frames are idealized using the concept of a lean-on column, where an elastic beam-column element with geometric stiffness is used to model the lean-on column. The section properties of the lean-on column are obtained by taking the sum of the section properties of each gravity column within the tributary area (i.e., one quarter of the floor plan) of the MRF and the DBF. The MR dampers are modeled using the MNS MR damper model implemented into OpenSees by Chae et al. (2010). The MR damper is assumed to be located between the top of the brace and the adjacent beam-column joint, as shown in Fig. 8. The results reported in this paper are for MR dampers that are passive controlled with a constant current input of 2.5 A. Studies with the MR dampers in semi-active control mode are presented in Chae (2011).

The gravity loads from the tributary gravity frames are applied to the lean-on column

to account for the $P-\Delta$ effect of the building. To model the effect of the rigid floor diaphragm, the top node of the panel zone element in the MRF and the beam-column joint in the DBF are horizontally constrained to the node of the lean-on column at each floor level, while the vertical and rotational degrees of freedom of these nodes are unconstrained.

Rayleigh damping is used to model the inherent damping of the building with a 5 % damping ratio for the first and second modes.

Comparison of Response

An ensemble of 44 ground motions listed in FEMA P695 (ATC 2009) is scaled to the DBE and MCE levels using the procedure by Somerville et al. (1997) for the NTHA.

A summary of the median and standard deviation of maximum story drift and residual story drift from the NTHA is given in Table 5. Figures 9 and 10 compare the calculated design demand for drift from the SDP with the median values for maximum story drift from the NTHA under the DBE and MCE ground motions. The story drift

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers, Table 5 Median and standard deviation of maximum and residual story drift from nonlinear time history analysis

Performance-Based Design Procedure for Structures with Magneto-Rheological Dampers,

Fig. 9 Comparison of story drift between SDP and NTHA, DBE ground motions

design demand calculated by the SDP shows good agreement in Fig. 9 with the median maximum story drifts from the NTHA. The calculated design demand for story drift from the SDP also shows good agreement with the median values from the NTHA under the MCE, see Fig. 10. Figures 9 and 10 show that the median values of the maximum story drift from the NTHA satisfies the performance objectives of 1.5 % and 3.0 % under the DBE and MCE levels, respectively. The residual story drift of the building after the DBE has a maximum median value and standard deviation of 0.22 % and 0.27 %, respectively, which occurred in the third story as summarized in Table 5. The residual drift is small.

Table 6 compares the design demand for maximum MR damper forces calculated by the SDP with the median maximum MR damper forces from the NTHA. The MR damper force design

demands from the SDP are slightly smaller than the median NTHA results for the DBE. However, the differences between the SDP and the NTHA are only 3.9 % and 3.3 % for the MR dampers in the second and third stories, respectively. For the MCE, the differences between the median NTHA results and the SDP for the MR damper forces in the second and third stories are 1.6 % and 0.5 %, respectively. The design demand calculated by the SDP shows reasonably good agreement with the median results from the NTHA for the maximum MR damper forces.

The linear elastic behavior of the DBF columns under the DBE is confirmed by checking the plastic rotation developed in the columns. Summarized in Table 7 are the median and standard deviation of the DBF maximum magnitude of column plastic rotation from the NTHA for the DBE ground motions. In the first story, some

	SDP	NTHA	SDP	NTHA
1	—	—	—	—
2	222.9	231.9 (6.4) ^a	244.4	248.4 (7.3)
3	233.6	241.5 (8.3)	261.6	260.2 (9.4)

^aValue in () indicates standard deviation response

plastic rotation developed at the base of the column under the DBE. However, the median is zero and the standard deviation is 0.0005 rad for the maximum plastic rotation. The median and standard deviation of the maximum plastic rotation in the second and third stories columns are zero under the DBE ground motion, as given in Table 7, which indicates linear elastic behavior of the columns at these stories. The median of the residual plastic rotation at the base of the column is zero and the standard deviation for the residual plastic rotation is 0.0004 rad.

The building’s response under the DBE and MCE determined by the NTHA appears to have met the performance objectives for the structure. Moreover, the performance under the DBE meets the immediate occupancy level (FEMA 2000b), where the maximum residual drift is practically equal to the allowable construction tolerance of 0.2 % for steel structures (AISC 2005a), with

minimal damage occurring in the building (the median of the maximum plastic rotations in the beams and columns of the MRF are 0.37 % and 0.07 % radians, respectively, with the MRF having the same residual drift statistics as the DBF due to the rigid diaphragm (Chae 2011)).

Summary

A simplified design procedure was developed to enable the performance-based design of structures with MR dampers. The design procedure utilizes a systematic approach to calculate the design demand of structures with MR dampers.

The simplified analysis procedure enables the design demand to be determined without performing a nonlinear time-history analysis by linearizing the structure and utilizing the response spectrum analysis method.

To linear the nonlinear MR dampers, the simplified analysis procedure is based on an equivalent linear MR damper model using the Hershel-Bulkley quasi-static MR damper model. The energy dissipated by the MR damper over one cycle of a harmonic motion is calculated and the equivalent stiffness determined based on the secant stiffness method from the damper force-displacement relationship. The loss factor of the MR damper is obtained from the energy dissipated by the damper and the strain energy calculated from the equivalent stiffness of the damper. Both the equivalent stiffness and loss factor of the MR damper are dependent on the maximum displacement of the damper. A three-story building was designed using the SDP, where three performance objectives associated with two seismic hazard levels were selected. The SDP was assessed by comparing the design demand calculated by the SDP with the response determined from nonlinear time-history analyses. The MNS MR damper model was implemented into the OpenSees computer program and statistics for the response to DBE, and MCE ground motions were obtained from a series of nonlinear time-history analyses using 44 different ground motions. The performance of the building from the nonlinear time-history analysis indicated that building design satisfies the three performance objectives. The design demand associated with story drift and maximum MR damper forces from the SDP showed good agreement with the median values from the nonlinear time-history analyses, confirming the robustness of the SDP.

Deterministic earthquake simulation; Deterministic ground-motion simulation; Physics-based earthquake simulation

Introduction

Physics-based earthquake ground-motion simulation, also referred to as deterministic earthquake ground-motion simulation, can be defined as the prediction of the ground motion generated by earthquakes by means of numerical methods and models that incorporate explicitly the physics of the earthquake source and the resulting propagation of seismic waves. Other approaches such as the stochastic ground-motion simulation method or ground-motion prediction equations (i.e., attenuation relationships) integrate the

physics and specific characteristics of the earthquake source, directivity, path, attenuation and scattering, basin, and site effects by means of indirect, approximate, or statistical approaches. These methods are valid representations of the physics of earthquakes, but do not necessarily solve the accepted mathematical abstractions that describe the physics of source dynamics and wave propagation. Physics-based ground-motion simulation, on the other hand, seeks to account for most or all of these aspects explicitly, thus the distinction given to its name.

This chapter reviews the background of physics-based ground-motion simulation, describes some of the most popular methods used in this field, and presents application examples. The first section focuses on the background of the method. The second section presents the concept of a physics-based simulation framework. Subsequent sections review the basic methods applied for the solution of seismic waves traveling in solids, including elastic, anelastic, and elastoplastic media, and provide details about the input data used in simulations (source and velocity models) while addressing other important complementary aspects in numerical modeling and computer simulation along the way. The final sections present recent examples and applications and a summary with a perspective on the future use of physics-based simulation in earthquake hazard analysis and engineering.

Background

The foundation for a physics-based approach to earthquake ground-motion simulation was laid down in the late 1960s and early 1970s when the finite-difference (FD) and the finite-element (FE) methods were first introduced in seismology (Alterman and Karal 1968; Lysmer and Drake 1972). Before numerical methods started to be more broadly used, only a few problems under restricted conditions could be solved analytically. Classical examples include the surface response of semi-cylindrical and semi-elliptical canyons and alluvial valleys under incident plane SH

waves (e.g., Wong and Trifunac 1974). Analytical approaches were, however, useful only to characterize the ground motion under idealized settings that neglected the geometrical irregularity of the geology and the heterogeneity of the media and were typically considered for sites away from the source, or with simplified source representations.

By contrast, FD and FE approaches offered more flexibility. They could be used to describe the propagation of waves in (irregular) stratified media, alluvial valleys, and sedimentary basins, assess ground-motion amplification, and study source dynamics (e.g., Boore 1972; Smith 1975). Initially, due to computational limitations, numerical methods were used mostly for solving two-dimensional (2D) problems. With time, advances in numerical methods and algorithms and the growth and increased availability of computing power and memory capacity allowed scientists to model larger and more complex 2D and small three-dimensional (3D) problems. Virieux (1984), in particular, introduced the staggered-grid FD scheme in the context of seismology, which would later become a preferred approach for modeling seismic wave propagation problems.

The first 3D simulations done at scales large enough to synthesize source, path, basin, and site effects were published in the early 1990s. Frankel and Vidale (1992), for instance, simulated the ground motion generated by an M_L 4.4 aftershock of the 1989 Loma Prieta, California, earthquake using a point source model and a FD representation of the Santa Clara Valley. The model had about four million nodes in a simulation domain of 30 km by 22 km and 6 km in depth. The synthetic seismograms obtained were valid for a maximum frequency, $f_{\max} = 1$ Hz, and the minimum shear-wave velocity ($V_{S_{\min}}$) considered was 600 m/s. Although the synthetics lacked the level of fidelity expected from direct comparisons with data, they were, in general, comparable in amplitude and duration. More important, the results of Frankel and Vidale (1992) showed that simulations offered a plausible means to understanding the characteristics of 3D wave propagation in highly heterogeneous media.

Following Frankel and Vidale (1992), FD applications gained significant traction (e.g., Olsen et al. 1995; Graves 1996). Some of these works were done using parallel computers. Olsen et al. (1995), for instance, simulated the ground motion of an M 7.75 scenario earthquake on the San Andreas Fault. The model covered the entire Greater Los Angeles metropolitan region in a simulation domain of 230 km by 140.4 km and 46 km in depth. The simulation was designed for $f_{\max} = 0.4$ Hz and $V_{S_{\min}} = 1$ km/s, using a grid spacing of 0.4 km. The resulting model had over 23.5 million grid points. This simulation was one of the first to use parallel computers for simulating the ground motion at a regional scale. It required nearly 23 h to complete 4,800 time steps on a 512-processor nCUBE-2 computer. Despite some limitations, Olsen et al. (1995) made important observations about the significance of 3D basin and edge effects that could not have been described at the time using only equivalent 1D or 2D models.

Similarly, FE applications were also developed for both source dynamics and wave propagation problems (e.g., Bao et al. 1998; Aagaard et al. 2001). Bao et al. (1998), for example, used a parallel computer FE application to simulate the ground response of the San Fernando Valley, California, to an aftershock of the 1994 Northridge earthquake. The FE mesh consisted of 76.8 million elements, with parameters $V_{S_{\min}} = 220$ m/s and $f_{\max} = 1.6$ Hz. The simulation required 7.2 h to execute 16,667 time steps (40 s of ground motion) on 256 processors in a Cray T3D machine. Bao et al. (1998) observed that, besides the larger amplitudes and longer durations associated with the deeper parts of the basin beneath the San Fernando Valley, the ground motion was also significantly amplified by the constructive interference of surface and trapped body waves in the shallower soft-material deposits.

Pseudo-spectral, high-order FE, spectral element (SE), and discontinuous Galerkin (DG) methods have also been used (e.g., Seriani 1998; Komatitsch and Vilotte 1998; Dumbser and Käser 2006). Some SE applications have been particularly successful in simulations at the continental and global scales. Komatitsch

et al. (2003), for instance, show results using a SE approach to model seismic waves propagating through the Earth's globe, including the full complexity of a 3D crustal model with a mesh of 5.5 billion grid points, for seismic periods as low as 5 s (i.e., $f_{\max} = 0.2$ Hz). By contrast, problems of small and moderate sizes continue to be addressed using analytical or semi-analytical methods with approaches such as the boundary element, coupled boundary-domain element, discrete wave-number, and hybrid methods (e.g., Bouchon 1979; Mossessian and Dravinski 1987; Bielak et al. 1991; Sánchez-Sesma and Luzón 1995).

More recently, the increased availability and power of parallel computers have facilitated enormously the advance of 3D physics-based earthquake ground-motion simulation. Chaljub et al. (2010) and Bielak et al. (2010), for example, show the tremendous advance by both Europe- and US-based research groups to conduct verification of simulation codes used for modeling the wave propagation characteristics of historic and scenario earthquakes. It is now commonplace to see simulation domains ranging in the order of tens to hundreds of kilometers, with total number of elements or cells in the order of tens to hundreds of billions. Maximum frequencies modeled today vary between 2 and 5 Hz for regional-scale ground-motion simulations and are as high as 10 Hz for smaller-scale rupture dynamics and local wave propagation problems (e.g., Cui et al. 2010; Taborda and Bielak 2013; Shi and Day 2013). In addition, the advent of newer technologies such as general purpose graphic processing units (GPGPU), hybrid CPU and GPU systems, and many integrated core (MIC) architectures are further helping to accelerate forward and inverse, regional and global wave propagation simulations (e.g., Komatitsch et al. 2010; Zhou et al. 2012; Rietmann et al. 2012).

Altogether, the progress shown over the past few years has opened the possibility of using physics-based ground-motion simulation in earthquake engineering applications. The framework for using simulations for a physics-based approach to regional seismic hazard mapping, for

instance, has already been put in place and is being used at low frequencies (up to 0.5 Hz) in Southern California (Graves et al. 2011). Some obstacles, however, still need to be sorted out. The present knowledge of the earthquake source, crustal structure, material properties, and local site effects is still far from ideal. All these aspects will require much research in the years to come, but the trajectory indicates that physics-based earthquake ground-motion simulation will play a significant role in future seismic hazard estimation, risk assessment, and earthquake engineering analysis and design.

The Physics-Based Simulation Workflow

Physics-based earthquake simulations operate within a basic general workflow that consists of the following elements or steps:

- The selection of a region of interest and simulation domain
- The selection of a source model and a material model
- The definition of the modeling parameters (maximum frequency, minimum velocity, etc.)
- The implementation of solution methods and operation of a simulation engine
- The execution of the simulation and collection of results

This simulation workflow is illustrated in Fig. 1. The top section of the workflow refers to the input data that is required for the simulation, that is, the selection of the simulation domain, the source model, the material model, and the simulation parameters. The source model provides information about the fault rupture characteristics in the form of its location, orientation, and slip history. Most physics-based earthquake simulations use kinematic models to represent the source as will be explained later. However, dynamic rupture simulations that fully solve the rupture evolution on the fault plane and the triggered wave propagation problem can also be combined with the simulation of the ground motion. The material model provides information

Physics-Based Ground-Motion Simulation,

Fig. 1 Typical workflow in physics-based earthquake ground-motion simulations. The *top* section (in yellow) refers to the input models and parameters; the *middle* section (in purple) refers to the solution method and implementation into the simulation engine; and the *bottom* section (in green) refers to the simulation execution and results

about the properties of the material contained in the chosen simulation domain. Material models are often referred to simply as seismic velocity models, as most of these models only provide information about the *P*- and *S*-wave velocities and the density of the medium. However, a complete description of the material also provides information about its dissipation properties and capacity. A later section is dedicated to the description of some publicly accessible velocity models. The last pieces of information at the input data level are the simulation parameters.

At the most basic level, these consist of the maximum targeted frequency in the simulation ($f_{\max}$, usually defined in Hz) and the minimum shear-wave propagation velocity ($V_{s\min}$, usually defined in m/s). Also relevant at this point is the definition of the number of points per wavelength, which is the integer number of points that will be used to discretize a complete wave cycle. Together, these parameters define the level of refinement or resolution necessary to solve the problem with a certain acceptable level of accuracy to the extent possible.

The second section in the workflow shown in Fig. 1 refers to the solution method and its implementation in a computer code application. Together, they provide a simulation engine that can be used in personal computers, clusters, or supercomputers. There are various simulation computer codes used in research today, some of which provide open-access distribution. A well-documented example of a code available to users is the SPECFEM software family, distributed by the Computational Infrastructure for Geodynamics project (<http://www.geodynamics.org>). Given the computing resources necessary for the solution of forward wave propagation simulations at regional scales, the implementation of such simulation engines in parallel computer codes and the use of computer clusters and supercomputers have become a commonplace in physics-based earthquake simulation. Until now, this has restricted the use of physics-based earthquake simulations to research-oriented activities. However, as the projected capacity of personal computers over the next 50 years will make parallel computing applications massively accessible to the public, it is expected that the use of these simulation codes and that of physics-based simulations overall will increase within the seismology and earthquake engineering communities in the near future. The last portion of the workflow shown in Fig. 1 makes reference to the execution of the simulation in itself and the gathering of results. Typical simulation output datasets come in three basic flavors: individual station records, plane wave fields, and volumetric wave fields. Station records are usually output in the form of text or binary files with velocities (or displacements) ordered sequentially at every time step. Plane and volumetric wave fields are commonly delivered as binary files indexed in such a way that they can be sliced in 2D and 3D arrays with the ground response for every time step. Simulators usually produced these outputs at a (decimated) time step that is larger than that actually used internally in the computation of the solution. Station records and plane wave field outputs are the most common of the three because their file sizes make them more manageable in terms of memory and disk space capacity.

A station record file is typically of the order of a few hundreds of kilobytes to a couple megabytes, and a plane file ranges between tens and hundreds of gigabytes. Volumetric wave fields, on the other hand, can reach the order of terabytes and thus become onerous to transfer and store.

The following sections expand on some of these aspects, including the most common solution methods, typical representations of source models, and seismic velocity models used in regional simulations, and provide examples about the use given to physics-based earthquake simulations today. Specific computer code applications are not covered here, although some basic principles about their numerical implementation in computer codes are covered in the sections dedicated to the solution methods used in physics-based simulation.

Wave Propagation in Elastic Media

As mentioned in the previous sections, there are various analytical and numerical methods used for solving wave propagation problems. The simulation of the ground motion at scale, that is, the simulation in domains large enough for synthesizing the earthquake source and the local and regional response of the ground, has, however, been primarily approached using FD, FE, SE, and, lately, DG methods. Since the formulation of both the SE and DG methods share some of the basic concepts of FE method, special attention is given here only to the FE and FD methods. This section covers these two methods applied to elastic media first. Subsequent sections address the problem of anelasticity and plasticity separately.

The Finite-Element Method

Earthquake ground-motion simulation entails obtaining the solution of the linear momentum equation, which can be written in Cartesian coordinates and indicial notation as

$$\sigma_{ij,j} + f_i = \rho \ddot{u}_i. \quad (1)$$

Here, σ_{ij} represents the Cauchy stress tensor, ρ is the mass density, and f_i and u_i are the body forces and displacements in the i direction within a bounded domain Ω . The two dots over the displacements indicate second derivative in time. The indices i and j in the subscripts represent the Cartesian coordinates x , y , and z . When a subscript follows a comma, this indicates a partial derivative in space with respect to the corresponding index. For the special case of elastic isotropic solids, the stress tensor can be expressed in terms of strains following Hooke's law of elasticity, and the strains, in turn, can be expressed in terms of displacements. The resulting expression for the stress tensor is

$$\sigma_{ij} = \lambda u_{k,k} \delta_{ij} + \mu (u_{i,j} + u_{j,i}) \quad (2)$$

where λ and μ are the Lamé parameters and δ_{ij} is Kronecker's delta. In general, the Lamé parameters in Eq. 2 and the density in Eq. 1 are assumed to be locally constant. Substituting Eq. 2 into Eq. 1 leads to

$$\lambda u_{k,kj} \delta_{ij} + \mu (u_{i,jj} + u_{j,ji}) + f_i = \rho \ddot{u}_i. \quad (3)$$

This is Navier's equation of elastodynamics. Using the standard Galerkin method, one can obtain the weak form of this equation and then discretize the problem in space. This procedure entails the introduction of set of arbitrary functions v , known as the test functions. The test functions are auxiliary functions which help formulate an approximate solution $\hat{u}$ to the displacements u , called the trial functions. The domain Ω is then discretized in space using a set of global piecewise linear basis functions ϕ , which divide the domain into discrete elements Ω_e . As a result, both the test and trial functions become linear combinations of the global basis functions,

$$v_h(x, y) = \sum_{i=1}^N \phi_i(x, y) v_i^h, \text{ and} \quad (4)$$

$$\hat{u}_h(x, y) = \sum_{i=1}^N \phi_i(x, y) \hat{u}_i^h, \quad (5)$$

respectively. Here, h is used to indicate that the domain Ω has been approximated to a discrete version of it, Ω_h , composed of all the elements with domain Ω_e , where h is a discretization parameter (e.g., element size). These elements Ω_e are connected to each other along their edges and at their vertices. The vertices of the elements are called nodes. Both the nodes and the elements constitute a FE mesh, where N is the total number of nodes. The index i indicates that the values of v and $\hat{u}$ are evaluated at the nodes using the associate global function ϕ_i . It can be shown that substituting Eqs. 4 and 5 into Eq. 3 leads to

$$\mathbf{M}\mathbf{u} + \mathbf{K}\mathbf{u} = \mathbf{f}, \quad (6)$$

where $\mathbf{M}$ and $\mathbf{K}$ are the assembled global mass and stiffness matrices of the system's discrete FE mesh representation, $\mathbf{f}$ is the assembled vector of body forces (which is determined based on the kinematic representation of the source – see the section “[Source Models](#)” below), and $\mathbf{u}$ is the assembled vector of displacements at the nodes in the FE mesh. Once again, the double dots over the displacement vector mean second derivative in time (i.e., acceleration). Not shown here for brevity is the fact that in following the FE method, the test function terms vanish. The matrices $\mathbf{M}$ and $\mathbf{K}$ and the vector $\mathbf{f}$ in Eq. 6 are composed of terms corresponding to the nodes of the elements in the FE mesh. The i th row and j th column terms in these matrices and vector are given by

$$\mathbf{M}_{ij} = \int_{\Omega} \rho \phi_i \phi_j d\Omega, \quad (7)$$

$$\mathbf{K}_{ij} = \int_{\Omega} (\mu + \lambda) \phi_i \phi_j^T d\Omega + \int_{\Omega} \mu \phi_i^T \phi_j d\Omega, \quad (8)$$

$$\mathbf{f}_i = \int_{\Omega} \phi_i f d\Omega. \quad (9)$$

However, the global matrices $\mathbf{M}$ and $\mathbf{K}$ are seldom constructed explicitly for the full simulation domain Ω . A common practice is, instead, to perform the products $\mathbf{M}\ddot{\mathbf{u}}$ and $\mathbf{K}\mathbf{u}$ at the element level Ω_e using local basis functions ψ_i instead of

the global basis functions ϕ_i . This leads to performing the products $\sum_e \mathbf{M}^e \ddot{\mathbf{u}}^e$ and $\sum_e \mathbf{K}^e \mathbf{u}^e$, where $\mathbf{M}^e$ and $\mathbf{K}^e$ are the mass and stiffness matrices of each finite element in the mesh, built using the local basis functions, and $\ddot{\mathbf{u}}^e$ and $\mathbf{u}^e$ are the corresponding acceleration and displacement vectors that have the nodes associated with each element.

When operations are done at the element level using local basis functions as just described, the system of ordinary differential equations in Eq. 6 can be rewritten as

$$\sum_e \mathbf{M}^e \ddot{\mathbf{u}}^e + \sum_e \mathbf{K}^e \mathbf{u}^e = \sum_e \mathbf{f}^e. \quad (10)$$

Here, the summation symbol means assembling of all elements e in the FE mesh. At any time step n , the acceleration $\ddot{\mathbf{u}}_n$ can then be expressed in terms of the displacements by applying second-order central differences. Then, for the n th time step in the simulation, Eq. 10 becomes

$$\sum_e \mathbf{M}^e \left(\frac{\mathbf{u}_{n-1}^e - 2\mathbf{u}_n^e + \mathbf{u}_{n+1}^e}{\Delta t^2} \right) + \sum_e \mathbf{K}^e \mathbf{u}_n^e = \sum_e \mathbf{f}_n^e, \quad (11)$$

where Δt is the size of the time step. Furthermore, the system can be uncoupled using a diagonally lumped mass matrix. In that case, the elements of the mass matrix are such that $m_{ij} = m_i$ for $i = j$ and $m_{ij} = 0$ for $i \neq j$. This allows the forward step-by-step explicit solution of the displacements at time step $n + 1$. The solution for each node i in the mesh can be written as

$$u_{n+1}^i = \frac{\Delta t^2}{m_i} f_n^i - (u_{n-1}^i - 2u_n^i) - \frac{\Delta t^2}{m_i} \left(\sum_e \mathbf{K}^e \mathbf{u}_n^e \right)_i, \quad (12)$$

where m_i is the mass lumped at node i , u_n^i is the displacement at node i and step n , and the summation within the parenthesis corresponds to the assembling of the stiffness contributions of all the elements that share node i .

Note that in the formulation presented in Eqs. 1 through 9, no mention was made about

the boundary conditions. In FE, the traction-free conditions at the free surface are naturally met and no special treatment is needed. For the lateral and the bottom faces of the domain, however, appropriate measures need to be taken to effectively diminish or vanish the occurrence of spurious reflections at the finite boundaries of the simulation domain. There are several alternatives to implement absorbing boundary conditions in FE applications. Perhaps the simplest of them all consists on placing dampers at the nodes on the boundaries designed to absorb compression and shear plane waves locally. This approximation, while far from ideal, has been used in large-scale simulations with minimum reflections and acceptable performance (e.g., Bielak et al. 2010). Other more accurate absorbing boundary conditions can be satisfied with the implementation, for instance, of the perfectly matching layers (PML) method (e.g., Ma and Liu 2006).

Equations 6 through 12 above provide the basic formulation for a forward wave propagation problem in an elastic medium in which the conditions imposed by the geometrical irregularities or the material's heterogeneity are approximated by means of an appropriate discretization of the simulation domain. In earthquake ground-motion modeling, the meshing criteria are determined based on the maximum simulation frequency ($f_{\max}$), the desired number of points per wavelength (p), and the local material properties defined by the shear-wave velocity (V_S). The size e of each element is set so that it satisfies the rule

$$e_{\max} \leq \frac{V_S}{p f_{\max}}. \quad (13)$$

The adequate numbers of points per wavelength depends on the type of finite element used and the level of accuracy sought in the simulation. Acceptable minimum values for p in the case of first-order (linear) elements vary between 8 and 12, but a minimum of ten points per wavelength is recommended, unless higher-order (quadratic) elements are used.

Adequately setting the size of elements, however, does not necessarily cover all the

Physics-Based Ground-Motion Simulation, Fig. 2 Conventional spatial grid for the velocity–stress FD scheme (Modified from Moczo et al. 2004)

geometrical and material irregularities present in simulation models, such as surface topography, material inhomogeneities, and internal structural interfaces. From a meshing point of view, the best alternative in FE to handle most of these problems is to work with conforming meshes. These are meshes that discretize the simulation domain adjusting both the shape and size of the elements – and thus the location of nodes – to conform to the specific characteristics in the geometry and material properties of the medium. Though powerful in this sense, conforming meshes are more difficult to build and require more memory (if the stiffness matrices of the elements are to be stored) or more computing time (if the stiffness matrices are to be rebuilt for each element at every time step). Nonconforming meshes, on the other hand, rely on the size of the element in order to capture, to a certain extent, the changes in the geometry and material properties of the media. While nonconforming meshes are very efficient because they can be tailored to use template elements whose stiffness matrices need to be computed only once and then scaled up based on material properties (e.g., Tu et al. 2006), this approach requires additional attention when it comes to handling sharp contrasts in material properties, discontinuities, or strongly irregular geometries. Some of these problems can be overcome using hybrid approaches that combine multiple element types or mixed meshing strategies (e.g., Hermann et al. 2011) or by means of special elements with extended or fictitious domains (e.g., Restrepo and Bielak 2014). A more detailed description of these alternatives, however, is out of the scope of this chapter.

Additional aspects pertaining to modeling the earthquake source and the effects of attenuation are discussed in subsequent sections.

The Finite-Difference Method

Attention is now given to the basic concepts and approach used for modeling wave propagation problems using the FD method.

In FD solutions, the derivatives in differential equations are approximated with finite differences computed over a discrete grid. Consider the case of a vertically propagating, planar *SH* wave in a horizontally layered medium. The plane strain approximation reduces the wave Eq. 3 to one dimension:

$$\mu \frac{\partial^2 u_x}{\partial z^2} + f_x = \rho \ddot{u}_x. \quad (14)$$

To eliminate the double derivatives, Eq. 14 is often expressed using the velocity–stress formulation:

$$\rho \frac{\partial v}{\partial t} = \frac{\partial \tau}{\partial z} + f_x, \quad (15)$$

$$\frac{\partial \tau}{\partial t} = \mu \frac{\partial v}{\partial z}, \quad (16)$$

where the velocity in the *x*-direction, $\dot{u}_x$, has been replaced with *v* and the shear stress component σ_{xz} with τ . FD solutions require discretization of both space and time on a numerical grid (Fig. 2). Partitioning the domain space using a mesh of $z_0, z_1, z_2, \dots, z_j$ with uniform increment Δz and the time using a mesh of $t_0, t_1, t_2, \dots, t_n$ with uniform increment Δt , the partial derivatives in Eq. 15 at point *j* and time step *n* may be approximated using

$$\frac{\partial v_j^n}{\partial t} \approx \frac{v_j^{n+1} - v_j^n}{\Delta t}, \quad (17)$$

$$\frac{\partial \tau_j^n}{\partial z} \approx \frac{\tau_{j+1}^n - \tau_j^n}{\Delta z}. \quad (18)$$

The approximations in Eqs. 17 and 18 use the forward difference formula. Substituting Eqs. 17 and 18 into Eq. 15 and omitting the body force term yield

$$\rho \frac{v_j^{n+1} - v_j^n}{\Delta t} = \frac{\tau_{j+1}^n - \tau_j^n}{\Delta z}. \quad (19)$$

Using analogous approximations for the temporal and spatial derivatives in Eq. 16 yields

$$\frac{\tau_j^{n+1} - \tau_j^n}{\Delta t} = \mu \frac{v_{j+1}^n - v_j^n}{\Delta z}. \quad (20)$$

By solving Eqs. 19 and 20 for v_j^{n+1} and τ_j^{n+1} , velocities and stresses at time $n + 1$ can be determined from the values at time n :

$$v_j^{n+1} = v_j^n + \frac{\Delta t}{\rho} \frac{\tau_{j+1}^n - \tau_j^n}{\Delta z}, \quad (21)$$

$$v_j^{n+1} = v_j^n + \frac{\Delta t}{\rho} \frac{\tau_{j+1}^n - \tau_j^n}{\Delta z}. \quad (22)$$

Solutions of the wave equation require knowledge of the initial velocities and stresses at time $n = 0$, v_j^0 and τ_j^0 , respectively. By using Eqs. 21 and 22 for all j , velocities and stresses can iteratively be determined for $n = 1, 2, 3, \dots$ until the desired time step.

The finite-difference scheme in Eqs. 21 and 22 is *conditionally stable*. The solution converges only if the Courant number

$$C = \frac{\beta \Delta t}{\Delta z} \leq C_{\max}, \quad (23)$$

where $\beta = \sqrt{\mu/\rho}$ is the shear-wave velocity and $C_{\max} = 1$ for the FD scheme in Eqs. 21 and 22. Equation 23 is called the *Courant–Friedrichs–Lewy* condition.

A disadvantage of the forward difference formula is that the approximations to the temporal Eq. 17 and spatial Eq. 18 derivatives are not

symmetric with respect to the grid point of interest. A more accurate approximation of the partial derivatives in Eq. 15 can be obtained using the *central difference formula*:

$$\frac{\partial v_j^n}{\partial t} \approx \frac{v_j^{n+1} - v_j^{n-1}}{2\Delta t}, \quad (24)$$

$$\frac{\partial \tau_j^n}{\partial z} \approx \frac{\tau_{j+1}^n - \tau_{j-1}^n}{2\Delta z}. \quad (25)$$

This leads to a numerical scheme that depends both on values from the current time step n and the previous time step $n - 1$:

$$v_j^{n+1} = v_j^{n-1} + \frac{2\Delta t}{\rho} \frac{\tau_{j+1}^n - \tau_{j-1}^n}{2\Delta z}, \quad (26)$$

$$\tau_j^{n+1} = \tau_j^{n-1} + 2\Delta t \mu \frac{v_{j+1}^n - v_{j-1}^n}{2\Delta z}. \quad (27)$$

To solve Eqs. 26 and 27, the initial values at $n = 0$ and $n = 1$ must be known. Additionally, storing the velocities and stresses from both the current and the previous time step increases memory requirements. Approximating the spatial derivatives with the central difference formula and the temporal derivatives with the forward difference formula may seem a convenient alternative. However, such a combination leads to a FD scheme that is *unconditionally unstable*, i.e., it will not converge regardless of the value of the Courant number C . The stability of a numerical scheme is often analyzed using the *von Neumann method*, which is based on Fourier decomposition of the numerical solution.

A more efficient numerical scheme is obtained by staggering the position of stresses and velocities on the temporal and spatial grid as shown in Fig. 3 (Virieux 1984). By shifting the grid position for the velocities v by $\frac{1}{2}$ grid point in time and also shifting the grid position of the stresses τ by $\frac{1}{2}$ grid point in space, Eqs. 15 and 16 can be approximated using

$$\rho \frac{v_j^{n+\frac{1}{2}} - v_j^{n-\frac{1}{2}}}{\Delta t} = \frac{\tau_{j+\frac{1}{2}}^n - \tau_{j-\frac{1}{2}}^n}{\Delta z}, \quad (28)$$

Physics-Based Ground-Motion Simulation, Fig. 3 Staggered spatial grid for the velocity–stress FD scheme (Modified from Moczo et al. 2004)

$$\frac{\tau_{j+1/2}^n - \tau_{j-1/2}^{n-1}}{\Delta t} = \mu \frac{v_{j+1}^{n-1/2} - v_j^{n-1/2}}{\Delta z}. \quad (29)$$

The required initial conditions for this scheme are the velocities at time $1/2$, $v_{1/2}$, and stresses at time 0, τ_j^0 . Moving forward, the stresses at time n are computed first using

$$\frac{\tau_{j+1/2}^n - \tau_{j+1/2}^{n-1}}{\Delta t} = \mu \frac{v_{j+1}^{n-1/2} - v_j^{n-1/2}}{\Delta z}, \quad (30)$$

and then the velocities at time $n + 1/2$ are determined using

$$v_j^{n+1/2} = v_j^{n-1/2} + \frac{\Delta t}{\rho} \frac{\tau_{j+1/2}^n - \tau_{j-1/2}^n}{\Delta z}. \quad (31)$$

The forward difference formula in Eq. 18 represents the first-order approximation to the first spatial derivative, while the central difference formula (25) represents the second-order approximation. Both schemes can be derived by replacing the functional values at $f(z_0 \pm \Delta z)$ with a Taylor expansion:

$$\begin{aligned} f(z_0 \pm \Delta z) &= f(z_0) \pm f'(z_0)\Delta z \\ &\pm f''(z_0) \frac{\Delta z^2}{2} \pm f'''(z_0) \frac{\Delta z^3}{3!} \\ &+ O(\Delta z^4). \end{aligned} \quad (32)$$

The order of a numerical scheme is determined by the order of the truncation error, which is defined as the difference between the exact solution and the finite-difference approximation. Higher-order approximations may also be derived. For example, the fourth-order approximation in space combined with the second-order approximation in time has become popular for simulating ground motion (e.g., Olsen 1994; Graves 1996).

All the FD schemes discussed above Eqs. 21, 22, 26, 27, 30, and 31 are explicit, i.e., the velocities (or stresses) at a given grid point and time step are derived only from stresses and velocities of the previous time step(s). In implicit FD schemes, the velocities (stresses) at a given time step depend on velocities and stresses from both the current and previous time step. Implicit FD schemes are more difficult to solve and not frequently used in ground-motion modeling.

FD solutions to the wave Eq. 3 in two and three dimensions approximate the spatial and temporal derivatives in the same way. In computational grids used for 2D and 3D FD solutions, each element in the velocity vector and the stress tensor may be staggered with respect to the other elements (e.g., Graves 1996).

The FD solution derived above discusses only wave propagation in a continuum. In a real-world situation, discontinuities will be encountered at the free surface, at the boundaries of the computational domain, and at the contact between two different media in a heterogeneous medium.

Such internal material discontinuities can be treated using a homogeneous or a heterogeneous approach. In a homogeneous approach, boundary conditions at or near interfaces are explicitly discretized using a separate FD scheme, which is not a trivial problem. Therefore, most ground-motion prediction applications use a heterogeneous approach, where only one FD scheme is used for all internal grid points regardless of their distance to internal interfaces (Moczo et al. 2004). Such heterogeneous approaches typically define effective material parameters to improve accuracy near interfaces (e.g., Zahradnik et al. 1993).

In the above example of a vertically propagating *SH* wave, consider the interface generated by a horizontally layered sedimentary deposit resting on top of a denser, higher-velocity bedrock.

Physics-Based Ground-Motion Simulation,

Fig. 4 Free surface defined to coincide with position of (a) shear stress and (b) velocity (Modified from Moczo et al. 2004)

Assume that the interface coincides with the grid point defining the stress $\tau_{j+1/2}$ in Fig. 3. It can be shown (Moczo et al. 2002) that the boundary conditions at the interface can be fulfilled by defining the shear modulus at the interface as the harmonic average of the shear moduli from the two connected media:

$$\mu_{j+1/2}^H = \frac{2}{\frac{1}{\mu_j} + \frac{1}{\mu_{j+1}}}. \quad (33)$$

If the interface coincides with the grid point defining the velocity v_j (Fig. 3), on the other hand, the density ρ at the interface Eq. 31 must be replaced with the arithmetic average of the two materials (Moczo et al. 2002),

$$\rho_j^A = \frac{1}{2} \left(\rho_j - 1/2 + \rho_j + 1/2 \right). \quad (34)$$

Similar averaging methods are implemented in most heterogeneous 2D and 3D FD codes used in research today (e.g., Graves 1996; Cui et al. 2010).

In contrast to FE methods, the free surface requires special attention in FD methods. The boundary conditions at the free surface specify that the shear stress vanishes, i.e., $\tau = 0$. In the simple 1D case described earlier, the location of the free surface can be defined such that it intersects the position of the shear stress (Fig. 4a) or the position of the velocity (Fig. 4b). In the former case, the shear stress at the surface is explicitly set to $\tau_0 = 0$ during each iteration, and the velocity half a grid point below the surface is

calculated using Eq. 31. If the free surface coincides with the position of the velocity, v_0 (Fig. 4b), antisymmetry is used to ensure the traction-free boundary condition at the free surface (Levander 1988):

$$\tau_{-1/2} = -\tau_{+1/2}. \quad (35)$$

When staggered finite-difference grids are defined in two and three dimensions, a planar free surface will intersect both stresses and velocities. In that case, both approaches are employed to ensure that stresses vanish at the free surface (e.g., Graves 1996; Gottschämer and Olsen 2001; Moczo et al. 2004).

Irregular (nonplanar) free-surface boundary conditions are far more difficult to implement in FD methods. Typically, such methods require a much finer sampling of the wave field for accurate results (e.g., Robertsson 1996; Ohminato and Chouet 1997).

Similar to FE methods, absorbing boundary conditions are required at the bottom faces of the computational domain. Both damping zones (e.g., Cerjan et al. 1985) and perfectly matched layers (e.g., Marcinkovich and Olsen 2003) have been implemented in FD codes for simulation of strong ground motion.

Intrinsic Attenuation and Plasticity

The methods for solving wave propagation problems just described apply only to linear elastic conditions. However, the accurate representation

of seismic waves requires the consideration of energy losses due to internal friction or intrinsic attenuation and, when earthquake induced deformations are large enough, those due to plastic deformation as well. Both these losses are important because their omission may lead to the overestimation of the amplification and duration of seismic waves in regions with high dissipative properties, for attenuation effects in general, and in regions with soft materials that have low yielding limits or are exposed to large-magnitude earthquakes, in the case of plastic deformation. This section deals with the basic most common approaches used to include realistic attenuation and plasticity in simulations.

Intrinsic Attenuation

The general formulation of the evolution of linear isotropic viscoelastic material in time is governed by the stress–strain relation, in which the stress can be expressed as a convolution of the strain rate with a relaxation function as in

$$\sigma(\mathbf{x}, t) = \int_0^t \varphi(\mathbf{x}, t - \tau) \dot{\varepsilon}(\mathbf{x}, \tau) d\tau, \quad (36)$$

which is equivalent to

$$\sigma(\mathbf{x}, t) = \varphi(\mathbf{x}, t) * \dot{\varepsilon}(\mathbf{x}, t) \quad (37)$$

or

$$\sigma(\mathbf{x}, t) = \dot{\varphi}(\mathbf{x}, t) * \varepsilon(\mathbf{x}, t), \quad (38)$$

where the symbol $*$ is used to represent the convolution integral. $\sigma(\mathbf{x}, t)$ and $\varepsilon(\mathbf{x}, t)$ are the stress and strain states at a point $\mathbf{x}$ in time t , and $\varphi(\mathbf{x}, t)$ is the corresponding stress relaxation function. Dots on top indicate derivatives in time. Equations 37 and 38 are the same because of the differentiation properties of convolution.

The solution of the wave propagation problem in viscoelastic media in the time domain which follows from the direct substitution of Eq. 36 in Eq. 1 is, however, inconvenient because that would entail the computation of a convolution term at every time step. Such an approach would require the storage of the complete strain

history, making the computational implementation of the viscoelastic problem practically intractable.

It is clear from Eq. 38 that the formulation of the viscoelastic problem in the frequency domain is, on the other hand, straightforward. Applying the Fourier transform, Eq. 38 becomes

$$\sigma(\omega) = M(\omega) \varepsilon(\omega), \quad (39)$$

where

$$M(\omega) = \dot{\varphi}(\omega) \quad (40)$$

is understood as a frequency-dependent viscoelastic modulus. Note that, for simplicity, the spatial variable ($\mathbf{x}$) has been dropped. In general, $M(\omega)$ is defined as a complex quantity and it is such that

$$\lim_{\omega \rightarrow 0} M(\omega) = M_R, \quad (41)$$

$$\lim_{\omega \rightarrow \infty} M(\omega) = M_U, \quad (42)$$

where M_R and M_U are defined as the relaxed and unrelaxed material viscoelastic moduli. They correspond to the long-term equilibrium and instantaneous elastic response of the material and together define the relaxation modulus:

$$\delta M = M_U - M_R. \quad (43)$$

In practice, the viscoelastic modulus is expressed in terms of the material's quality factor $Q(\omega)$, which is defined as

$$Q(\omega) = \frac{\Re[M(\omega)]}{\Im[M(\omega)]}. \quad (44)$$

Understanding the formulation of anelasticity in the frequency domain facilitates its implementation in the time domain – where the system does not have to be fully assembled as in the frequency domain. The challenges in the formulation of the anelastic wave propagation problem in the time domain are (i) to solve the convolution term efficiently and (ii) to satisfy the behavior of the

Physics-Based Ground-Motion Simulation, Fig. 5 Examples of rheological models used to incorporate the effect of attenuation. (a) Generalized Maxwell model (Emmerich and Korn 1987), (b) generalized

Zener body (Carcione et al. 1988), and (c) a generalized Maxwell model augmented with a viscous damper (Bielak et al. 2011)

quality factor Q in the frequency domain – which for the range of frequencies typically covered by most simulations is considered to be constant in the low frequencies and frequency dependent in the higher frequencies.

Two particular works established the ground for most current approaches used to model the effects of anelasticity in time-stepped solutions (for frequency-independent Q): Liu et al. (1976) and Day and Minster (1984). Liu et al. (1976) were the first to use a rheological model made of a set of mechanical bodies (Zener mechanisms) in the context of seismic problems; and Day and Minster (1984) showed that if $M(\omega)$ is expressed as a rational function, then its inverse form in the time domain can be solved numerically – which then led to the formulation of efficient algorithms to account for anelastic losses.

Following the ideas set forth by Day and Minster (1984), in which a set of internal memory variables are used to represent the relaxation process, others have formulated memory-efficient approaches to anelastic wave propagation simulation using FD and FE approaches (e.g., Day and Bradley 2001; Ma and Liu 2006).

Emmerich and Korn (1987) proposed the use of a rational function $M(\omega)$ corresponding to a rheological model composed of a set of Maxwell bodies in parallel and a Hooke element also in parallel. They defined this model as the generalized Maxwell body (GMB) (Fig. 5a). Similarly, Carcione et al. (1988) employed a generalized Zener body (GZB) (Fig. 5b). Various separate implementations have been inspired in these two models, which were later shown to be equivalent (Moczo and Kristek 2005). Some implementation examples using FD, DG, and SE methods are those described in Chaljub et al. (2010). Most of these are formulated in terms of stresses and strains. More recently, Bielak et al. (2011) introduced a memory-efficient internal friction approach solely based on displacements more suitable for FE. The model proposed by Bielak et al. (2011) uses a set of Maxwell elements in parallel and a Voigt element also in parallel (Fig. 5c).

To correlate the problem of anelastic attenuation with the solution of the wave propagation problem in elastic media shown in the previous section, the model proposed by Bielak et al. (2011) is summarized next for the case of

a FE approach. Consider a semidiscretized version of the equations of elastodynamics where a mapping operator T is introduced to modify the displacements associated with the internal body forces as in

$$\mathbf{M}\ddot{\mathbf{u}} + \sum_e [\mathbf{K}^e(T\mathbf{u})^e] = \mathbf{f}. \quad (45)$$

Here, T is such that it represents the convolution term used in the stress–strain relation, which after applying finite elements becomes the stiffness–displacement product $\mathbf{K}^e(T\mathbf{u})^e$ given by

$$\mathbf{K}^e(T\mathbf{u})^e = \mathbf{K}^e \left[\mathbf{u}^e + \beta^e \dot{\mathbf{u}}^e - \sum_j \alpha_j^e \beta_j^e \exp(-\gamma_j^e t) * \mathbf{u}^e \right]. \quad (46)$$

Note that the convolution term is still present in Eq. 46. This term is replaced by the auxiliary memory variable φ , such that at any time step n with a discrete time-width Δt , the product $\mathbf{K}^e(T\mathbf{u})^e$ is given by

$$\mathbf{K}^e(T\mathbf{u})^e = \mathbf{K}^e \left[\mathbf{u}^e + \beta^e \frac{\mathbf{u}_n^e - \mathbf{u}_{n-1}^e}{\Delta t} - \sum_j \alpha_j^e \beta_j^e (\varphi_j^e)_n \right], \quad (47)$$

where

$$\begin{aligned} (\varphi_j^e)_n = & \frac{\Delta t}{2} \left[(1 - \Delta t \gamma_j^e) \mathbf{u}_n^e + \mathbf{u}_{n-1}^e \right] \\ & + \exp(-\gamma_j^e \Delta t) (\varphi_j^e)_{n-1}. \end{aligned} \quad (48)$$

α , β , and γ are constants associated with the mechanical elements of the adopted model (i.e., spring and dashpot constants) that are determined for each finite element e based on the quality factor Q of the material contained in the element. These constants can be derived separately for the quality factors associated with the propagation of P and S waves, Q_P and Q_S . Details about the particular implementation of this model can be found in Bielak et al. (2011). Information about the derivation of the values of Q_P and Q_S is provided in the section on “Material Models”.

Plasticity

The problem of wave propagation in elastoplastic and elasto-visco-plastic media has also been considered in 3D physics-based earthquake simulations, but has not yet reached the same level of maturity as anelastic wave propagation. This is mainly due to the computational complexity involved in incorporating full 3D nonlinear soil behavior in the solution scheme and the entailed computational overhead both in memory and processing time – as well as the difficulty to accurately reproduce ground motions in the frequency ranges where plastic behavior is believed to be more relevant (above 0.5 Hz).

Numerical modeling of the response of nonlinear sedimentary deposits also dates back to the 1960s and 1970s. Initial simulations considered 1D and 2D models and used linear equivalent methods to approximate the stress–strain relationship (e.g., Idriss and Seed 1968). Although the linear equivalent method continues to be used extensively in engineering research and practice, it has long been understood that it does not capture all the characteristics of nonlinear plastic behavior. Alternatively, there exist an abundant number of models based on more rigorous methods (e.g., Prevost 1978) to describe the cyclic stress–strain behavior of geomaterials. However, such models are usually defined in terms of material parameters upon which there is no consensus. In addition, they tend to be computationally expensive. This has made it difficult to apply rigorous plastic models in 3D regional earthquake simulations where the computational aspects are critical and the knowledge about the material properties at regional scales is limited – especially for the near-surface layers, where nonlinear soil effects are more significant.

An approach used to overcome the computational difficulties of incorporating near-surface plastic effects in physics-based simulations has been the combination of 3D linear elastic or anelastic simulation results with 1D nonlinear analyses of the incident motion at the interface between the bedrock and the sedimentary deposits (e.g., Roten et al. 2012). Hybrid

simulations, however, cannot completely describe the 3D aspects present when off-fault and near-surface plasticity is combined with the source, path, and basin effects. Alternatively, there have been successful first approximations to obtain full 3D regional-scale simulations that consider plastic deformations using computationally tractable material models such as the classical Drucker–Prager yield criterion (e.g., Dupros et al. 2010; Taborda et al. 2012; Roten et al. 2014). Although the material models used in these simulations do not accurately reproduce the elasto-visco-plastic behavior of most geomaterials, they are useful to understand the 3D nature of nonlinear wave propagation in heterogeneous media.

Following the formulations presented before for the case of the FE method, the solution of the wave propagation problem in plastic media can be described as follows. Consider the semidiscretized version of Navier’s Eqs. 1 through 6, but in a manner in which the stresses are preserved explicitly. In that case, Eq. 6 becomes

$$\mathbf{M}\ddot{\mathbf{u}} + \sum_e \int_{\Omega_e} \mathbf{B}^T \boldsymbol{\sigma} d\Omega_e = \mathbf{f}, \quad (49)$$

where $\mathbf{B}$ is the strain matrix and $\boldsymbol{\sigma}$ is the stress tensor over element Ω_e . The summation, again, means assembling of elements.

Some important points need to be noticed about Eq. 49. See that in order to obtain the contribution of the internal forces given by the product $\mathbf{B}^T \boldsymbol{\sigma}$ in the integral term, one must know the state of stresses. The stresses, however, depend on the state of total strain in the material ($\boldsymbol{\varepsilon}$), and the strains, in turn, need to be compatible with the stresses themselves according to the constitutive model chosen to represent the material’s plastic behavior. In the elastic problem, this relationship between the stress and strain tensors is linear. In plasticity, on the contrary and in general, it is not. Therefore, it follows from this that, embedded within the time integration of Eq. 49, there is a nonlinear problem that requires the implementation of an implicit solution

scheme, which in most cases requires additional computational effort.

In general, following the classical theory of plasticity, the total strain ($\boldsymbol{\varepsilon}$) can be expressed in terms of the sum of the elastic ($\boldsymbol{\varepsilon}^e$) and plastic ($\boldsymbol{\varepsilon}^p$) deformation components,

$$\boldsymbol{\varepsilon}_{ij} = \boldsymbol{\varepsilon}_{ij}^e + \boldsymbol{\varepsilon}_{ij}^p. \quad (50)$$

This is useful because one can then express the associated admissible stress in terms of the product of the elastic stiffness tensor (D) and the elastic strain,

$$\sigma_{ij} = D_{ijkl} \varepsilon_{kl}^e. \quad (51)$$

Equations 50 and 51 also need to be thought carefully. In solving Eq. 49, at any given time step, one can obtain the total strain from the current state of displacements. The objective then becomes finding its plastic and elastic components, so that the stress given by Eq. 51 remains compatible with the constitutive model and the total strain. Considering that by definition the elastic deformation component is bound to the stresses by the elastic stiffness tensor – as opposed to the plastic deformation which is unbounded in general – the critical point becomes finding the corresponding plastic deformation $\boldsymbol{\varepsilon}^p$.

This is where the choice of the material model plays its role. Constitutive models provide the means for tracking the progress of the plastic deformation through the combination of a yielding potential function (g) and the rate of the plastic strain ($\dot{\boldsymbol{\varepsilon}}_{ij}^p$) – that is, a function of how the plastic strain changes in time. Yielding potential functions are of the form

$$g(\sigma_{ij}, k) = F(\sigma_{ij}) - k(\sigma_{ij}, k_n) < 0, \quad (52)$$

where F represents the current state of stresses and k defines the hardening characteristics of the material. At the upper limit of Eq. 52, $F - k = 0$ represents a yielding surface which defines the plastic state of the material. In other words, the yielding surface provides a limiting state on which a material’s particle must remain while in

a plastic deformation condition. Below this surface, the particle behaves elastically, and on the surface, plastically. Here, the hardening characteristics controlled by k refer to the ability of some materials to regain strength after they have gone over the plastic domain. In perfectly elastoplastic materials, for instance, the yielding surface can be thought of as being “flat” and k is null. In materials with hardening characteristics, on the other hand, the yielding surface changes depending on the state of deformation. That is why k is also a function of σ . k_n is used here generically to represent the material parameters controlling hardening.

As noted in Eq. 52, both F and k are functions of the stresses and therefore depend on the plastic state of deformation. It follows from Eqs. 50, 51, and 52 that the key component toward finding the solution of Eq. 49 is determining the state of plastic deformation, which is given by the plastic potential strain rate:

$$\dot{\epsilon}_{ij}^p = \dot{\lambda} \frac{\partial h(\sigma_{ij}, k)}{\partial \sigma_{ij}} = \dot{\lambda} \frac{\partial g(\sigma_{ij}, k)}{\partial \sigma_{ij}}, \quad (53)$$

where $\dot{\lambda}$ is a plastic multiplier and h is a function which defines the plastic potential. As noted in the right-hand side of Eq. 53, for simplicity, h is a function similar to and often assumed to be the same as the yielding potential function g explained before. The plastic multiplier $\dot{\lambda}$ sets the magnitude of the plastic deformation in the current state of stresses as a material’s particle moves over the yielding surface.

As it can be inferred from this description, the solution of Eq. 49 leads to additional computations to help ensure that the stress–strain relationship is maintained according to the nonlinear constitutive model of choice. This requires the use of implicit solution schemes, as opposed to the explicit approach used in the elastic and viscoelastic problems. This additional effort explains why considering the material’s plastic behavior in physics-based ground-motion simulations in 3D has often been ignored or simplified using hybrid and indirect approaches. Future developments, however, are likely to revert this

trend, and progress is expected to be done in this area in the near future.

Source Models

As seen in the simulation workflow section, physics-based earthquake simulations depend on two basic models used to represent the earthquake itself and the propagation media, these are the source model and the material model, respectively. They, in turn, define the characteristics of the applied and internal body forces in the formulation of the solution of the wave propagation problem. This section deals with the basic concepts of source models used as input to earthquake simulations.

The fault’s rupture and the resulting wave propagation problem are seldom solved together in a single simulation, especially at regional scales. This is mainly due to the complexity of the rupturing process on the fault, which entails a multi-physics problem with plastic deformation and/or the use of dislocation models to represent the loss of friction/contact on the fault’s surface. Source models are, instead, resolved prior to performing the simulation of the ground motion and then treated in the simulation as basic input data as seen in the simulation workflow section. Some common alternatives from where source models are derived include:

- Source inversion studies
- Dynamic rupture simulations
- Pseudo-dynamic rupture generators
- Kinematic source model generators
- Basic geologic and seismogenic information about the fault

Regardless of the method employed to obtain the source model, the most common approach used in simulations is to convert the source model into a kinematic source representation, that is, a model that represents the source as a set of equivalent forces (or stresses) that are applied to the forward simulation model to trigger the propagation of seismic waves. These equivalent body forces are such that they produce

a displacement field away from the source that is equivalent to that one would have obtained using a more rigorous solution for the source if embedded in the simulation.

In the case of small-magnitude earthquakes ($M < 5$) or sources small enough compared to the wavelength of the radiated energy, the effect of the earthquake rupture and the discontinuity of displacements that occurs at the fault can be modeled using a single set of self-balanced (double-couple) forces acting on a point, that is, a *point source* model. In the case of large-magnitude earthquakes, on the other hand, the rupture occurs over extended areas on the fault's surface and thus cannot be treated as a point source. In such cases, the earthquake is modeled as the sum of many point sources. The approach relies on the idea that it is possible to discretize the fault's ruptured area into a collection of smaller subfaults, each with an assigned point source model. The subfaults are such that they adjust to the geometry of the entire fault and the collective action of the point sources adds up the right amount of energy release, equivalent to that of the complete earthquake model. Extended fault models composed of multiple subfaults are called *finite slip* or *finite source* models.

In both point and extended fault models, the point source at each (sub)fault is defined in terms of its geometry and rupture characteristics. These are given by:

- The location given in latitude, longitude, and depth
- The orientation given by the strike, dip, and rake angles of the (sub)fault
- The (sub)fault's area and average shear modulus of that area
- The evolution of the slip on the (sub)fault with time

Figure 6 shows an example of a kinematic source model. Part (a) shows the total slip distribution on the fault plane of the source model by Graves and Pitarka (2010) for the 1994 M_w 6.7 Northridge, California, earthquake. This model is composed of 140×140 subfaults with strike and dip angles of 122° and 40° , respectively, and

variable rake angle with an average of 101° . Part (b) shows the concept of the discrete subfault as used in a kinematic finite slip model in which each rectangular (or triangular) patch on the fault plane has an independent geometry (area, strike, dip, rake) and slip (as a function of time). And part (c) shows a typical slip velocity function, which is the function that defines the history of slip associated with the point source in each subfault area.

Point source models used in physics-based simulations can be simply built based on the earthquake focal mechanism and the selection of an appropriate slip function such as that shown in Fig. 6c. Extended fault models, on the other hand, are available from source inversions and rupture generators, and distributed in various formats. The US Geological Survey Earthquake Hazards Program, for instance, offers finite fault models for significant earthquakes in its Historical Earthquake Information database Web portal. Another useful source of fault models is the Finite-Source Rupture Model Database (SRCMOD) maintained by the eQuake-RC project Web site (<http://equake-rc.info/>). Models distributed by SRCMOD are contributed by researchers from all over the world and distributed in a set of common data files that include basic metadata and simple single-rupture-plane source-model representations. Another popular distribution format among modelers, especially in the USA, is the Standard Rupture Format (SRF) used by Graves and Pitarka (2010). The SRF encapsulates the rupture process in a single (ascii) text file that can have multiple fault planes and subfaults with variable geometry.

One important aspect to note as simulations advance toward higher frequencies is the influence that the source type and source model description have on the characteristics of the ground motion. If seen in the frequency domain, for instance, the slip-rate function of a single point source (as that shown in Fig. 6c) will reveal that the energy of the slip is mostly contained below a certain frequency. This, together with the seismic velocities represented in the model, will influence the energy distribution of the ground motions in the frequency domain,

Physics-Based Ground-Motion Simulation, Fig. 6 Example of a kinematic source model: (a) finite slip representation of the 1994 M 6.7 Northridge earthquake composed of 140×140 subfaults (Modified after

Graves and Pitarka 2010), (b) subfault model concept for a double-couple point source with independent geometry and source-time function, and (c) a typical slip-rate function in time

provided models are built with appropriate accuracy. In other words, and it should come as no surprise, the source spectrum is important in determining the frequency content of the ground motion.

Furthermore, in extended source models, the smoothness and homogeneity of the subfault characteristics also influence the outcome. If the distribution of total slip on the subfaults is fairly homogeneous, or if the evolution of the slip through the fault plane follows a certain pattern in space and time, then the wave field will evolve more smoothly as it travels away from the source plane. It will be more coherent. On the other hand, if each subfault slips randomly, the ground motion will be less coherent, and waves will be more likely to interfere with each other as they travel away from the fault. Similarly, the orientation of the slip on the plane, given by the rake angle, will dictate the strength of directivity effects. Additional complexity can be introduced if we also consider the fact that subfaults do not necessarily have to be aligned. Figure 5a depicts extended source models as a collection of point sources with variable rake angle and slip, but

constant strike and dip angles, with all the subfaults being part of a single fault plane. In reality, however, faults are not smooth planes, but irregular contact areas. This increases the variability of the ground motion considerably, as shown by recent models developed by Shi and Day (2013) to account for the geometrical heterogeneity (roughness) of the fault.

As mentioned above, these are all important factors that modelers need to consider, especially when simulating ground motions at high frequencies (>1 Hz), because short wavelengths can better capture the variations of the fault structure and rupture characteristics.

Material Models

Provided a source model, the second necessary component for a simulation is the material model, which defines the mechanical properties of the propagating media in the modeling domain. The most basic 3D material model used for elastic wave propagation simulations defines the material density (ρ) and seismic velocities of P and S waves

(V_P and V_S , respectively) at any arbitrary point within the simulation domain. Anelastic simulations require, in addition, the attenuation properties of the propagating media. The material's attenuation properties are defined in terms of the quality factors Q_P and Q_S associated with the attenuation characteristics of P and S waves, respectively. These quality factors are defined using attenuation rules or attenuation relationships which, in the context of physics-based ground-motion simulation, are empirical functions based on the values of V_P and/or V_S . For elastoplastic simulations, material models must also provide the parameters that define the characteristics of the adopted nonlinear constitutive model. Since elastoplastic material properties are unique to the adopted constitutive model, they are not described here; besides, complete definitions of all the mechanical properties of the propagating media in a single model are uncommon. Instead, for the case of anelastic ground-motion simulation, material models are divided in two parts: (a) seismic velocity models and (b) attenuation relationships. These are described next.

Seismic Velocity Models

Seismic velocity models, also known as community velocity models (CVMs), are datasets or computer programs that define the values of V_P , V_S , and ρ at any point in a particular region of interest. The point's location is usually expressed in terms of latitude, longitude, and depth (with respect to the free surface) or elevation (with respect to the sea level). Internally, CVMs are built using different types of datasets, which may include but are not limited to:

- Source inversion studies
- Surface topography or digital elevation maps
- Subsurface topography or geological horizons
- Gravity observations and refraction surveys
- Teleseismic and 3D tomographic inversions
- Mantle and Moho 1D background models
- Empirical rules correlating V_P , V_S , and ρ
- Shallow and deep boreholes and observations from oil wells

- Geotechnical layer models based on indirect measures (e.g., V_{S30} data)
- Random media representations

Some velocity models are built using voxels (volume elements) that define homogeneous 3D regions. Other models combine different datasets using interpolation rules that assign weights based on the location of the point of interest relative to the data points.

Most CVM computer codes are not necessarily optimized to work seamlessly with earthquake simulation codes. Modelers use additional tools to convert the data retrieved from a given CVM into grids or meshes. One particular tool of the sort is the unified community velocity model (UCVM) software framework (Small et al. 2015). UCVM is a collection of software tools developed and maintained by the Southern California Earthquake Center (SCEC) to provide an efficient and standard access to multiple, alternative velocity models. Although UCVM was primarily built to manage the SCEC community velocity models CVM-S and CVM-H for Southern California (Fig. 7), it supports and can be used to register other models as well.

There exist a good number of velocity models available to the community. It is, however, not possible to cover them all here in detail. A selection of some of the most relevant models used in simulations in the USA, Europe, and Japan is summarized in Table 1.

As simulations aim to produce more realistic ground motions comparable to observations, an important aspect in the construction and use of velocity models is that of the representation of the geotechnical layers and the variability of the material properties at small scales. For the most part, despite their level of detail, seismic velocity models tend to be smooth representations of the crustal structure. This is primarily due to the fact that geologic, exploration, and other survey data are only available at coarse resolutions. Modelers need then to resort to other methods to represent the presence of near-surface soft-soil deposits and the random characteristics of geomaterials. The presence of soil deposits is typically handled by introducing some kind of geotechnical layer

Physics-Based Ground-Motion Simulation, Fig. 7 Comparison of the two Southern California community velocity models CVM-S and CVM-H. Depth of

the major basins in the Greater Los Angeles region (in meters) as inferred from the isosurface for $V_S = 1.5$ km/s

model (GTL), which softens the transition from the rock basement to the surface. GTLs use empirical rules to estimate the near-surface (V_{S30}) seismic velocities and then interpolate the material properties from surface to depth. The interpolation is parameterized using existing

borehole profiles (Ely et al. 2010). The variability of the medium, on the other hand, is introduced by means of random spatially correlated perturbations to the model at small-scale resolutions (Hartzell et al. 2010; Withers et al. 2013). Both these elements have shown to have a significant

effect on the ground motion, especially at higher frequencies, thus their importance in the future of physics-based simulation.

Attenuation (Q) Relationships

As mentioned before, the quality factors associated with P and S waves, Q_P and Q_S , are most commonly defined based on the values of the seismic velocities V_P and V_S . The value of Q_S is usually defined from rules that depend directly on the value of V_S . Typical forms of Q_S – V_S relationships are piecewise linear and continuous polynomial functions. The value of Q_P , on the other hand, is usually defined in terms of Q_S and, in some cases, in terms of the velocity contrast V_P/V_S . Table 2 shows a collection of different Q_S – V_S and Q_P – Q_S relationships used in simulations. Each relationship is listed along with a publication, the earthquake or scenario event for which they were employed, and the minimum shear-wave velocity $V_{S_{\min}}$ and maximum frequency ($f_{\max}$) that was used in the associated simulations. Some of the references provided in Table 2 include notes (see superscripts) to clarify the nature, region, or scope within which the relationship was introduced or used. The FD and FE superscripts, in particular, indicate when a reference is being cited specifically in reference to the results published therein using one of these methods. Aagaard et al. (2008) or Bielak et al. (2010), for instance, include simulations using several methods; thus the superscripts indicate which method was used with the relationship associated with these studies.

As it can be seen from this table, there is no consensus on the most appropriate set of relationships between seismic velocities and quality factors. Notice also that the majority of the relationships are independent of depth (z) and all are independent of the frequency, even though it is known that these relationships are both depth and frequency dependent.

Here, the frequency dependence of Q is particularly important as it is understood to be of greater significance at frequencies above 1 Hz. Up until recently, this was not a major factor in physics-based ground-motion simulation because

simulations were typically done for maximum frequencies no greater than 1 Hz. However, with the increasing capacity of supercomputers, modelers are now more often being able to simulate ground motions at higher frequencies, thus its relevance in future efforts. In this case, the main ideas of the viscoelastic methods described in the “[Intrinsic Attenuation](#)” section will still apply, as they are formulated in frequency. Their current implementation in computer codes used in simulations, however, had been usually calibrated to adjust to constant target values of Q . Therefore, in years to come, the implementation of these viscoelastic models and the relationships shown in Table 2 will need to be revised to offer a consistent approach to modeling high-frequency (0–10 Hz) ground motions. This is a topic of current research and ongoing efforts such as those reported by Withers et al. (2014) offer a glimpse of the future in this regard.

Recent Examples and Applications

There is an ample spectrum of physics-based simulations available in the literature. Most of them have been published over the last two decades after supercomputing centers open for public research became available in the mid- to late 1990s and early 2000s, which boosted the capacity of modelers to conduct regional-scale simulations at resolutions not possible before parallel computer codes were developed and tested. Some of these simulations have already been cited to illustrate the various aspects involved in physics-based simulation. However, they cannot all possibly be covered here, thus only a small selection is addressed next. The selection includes examples of scenario and real earthquake simulations that have been used in verification and validation studies; those are the simulations of the Great Southern California ShakeOut and the 2008 Chino Hills, California, earthquake. Also covered here to a lesser extent is the application of physics-based simulation as a tool to construct a physics-based framework for probabilistic seismic hazard analysis, as it is done in the CyberShake project of the Southern California Earthquake Center.

Physics-Based Ground-Motion Simulation, Table 2 Examples of Q_S – V_S and Q_P – Q_S relationships used in past physics-based simulations. Most of these correspond to the region of Southern California and to past earthquakes, unless noted differently. FD and FE superscripts indicate when a publication is cited specifically in reference to results published therein using a particular method

ShakeOut

The 2008 Great Southern California ShakeOut was a multidisciplinary earthquake preparedness and emergency management exercise involving Earth science, engineering, and social sciences which has now transcended to an annually repeated drill held in many other US and worldwide seismic regions. In its first edition, the ShakeOut included the definition of an M 7.8 scenario earthquake rupturing the southern segment of the San Andreas Fault. The regional ground motion over an area of 600×300 km covering all major cities in Southern California for the ShakeOut scenario was computed using physics-based ground-motion simulation. A physics-based approach was chosen over empirical ground-motion prediction equations because the latter were considered poorly constrained for such an event. Details about the scenario and results can be found in Jones et al. (2008). The predicted ground motions helped estimate the dynamic response of buildings, losses, casualties, and the socioeconomic impacts of such an earthquake and are described in a special issue of *Earthquake Spectra* (Porter et al. 2011).

The simulations of ground motions for the ShakeOut were independently carried out by three different groups. Two groups employed

FD codes and one group used a FE code. The results were presented in Bielak et al. (2010) and verified using different comparison methods. Ground motions predicted by the three codes (Fig. 8) were found to be in good agreement with each other independently of the differences between the three code implementations. The analysis of the ground motion revealed very strong (>3 m/s) shaking near the fault and damaging ground motions (>0.5 m/s) over large areas of Los Angeles, San Bernardino, and Riverside (Jones et al. 2008). Strong long-period ground motions (>1 m/s) were also anticipated for the Los Angeles Basin, where significant damage and potential collapse was interred for older high-rise buildings. These strong amplifications were attributed to surface waves channeled along a chain of sedimentary basins acting as a waveguide, which had been previously observed during a similar simulation for the TeraShake scenario earthquake (Olsen et al. 2006).

Also based on ShakeOut simulation results, Graves (2008) reported large variations in Los Angeles Basin ground-motion levels resulting from small ($\sim 15\%$) adjustments to the rupture velocity. Olsen et al. (2008) had demonstrated that replacing the kinematic rupture models with spontaneous rupture models reduces PGV extremes in the region by a factor of 2–3 and attributed these

Physics-Based Ground-Motion Simulation, Fig. 8 Region of interest and surface projection of the simulation domain used in the ShakeOut scenario with a superimposed still image of the ground velocity halfway the rupturing segment of the San Andreas Fault (left), and

comparison of horizontal magnitudes of peak ground velocities obtained from the three simulation sets corresponding to the two finite-difference and one finite-element codes (After Bielak et al. 2010)

reductions to the less coherent wave field excited by dynamic rupture models. Day et al. (2012) identified the segment between the Cajon Pass and the northern Coachella Valley as the main contributor to amplification in the Los Angeles Basin, with the highest excitation resulting from super-shear (or energetically forbidden sub-shear, super-Rayleigh) rupture speeds. These studies have suggested that the level of shaking in the Los Angeles region during a large ShakeOut-type earthquake will depend strongly on the details of the source and warrant more research into the physics of the rupture process and the wave propagation, yet they are excellent examples of the reach of physics-based earthquake simulation as a tool to gain insight about the seismic conditions of regions prone to large-magnitude earthquakes.

2008 M_w 5.4 Chino Hills Earthquake

In contrast to the simulation of scenario earthquakes such as the ShakeOut, the simulation of the wave propagation from past events offers the additional possibility of validating deterministic ground-motion prediction results against recorded data. Various examples of validation of past earthquakes are available for low frequencies ($f < 0.5$ Hz), where physics-based simulations have shown to perform best (e.g., Komatitsch et al. 2004). On the other hand, there are efforts to advance the simulation of earthquakes using fully deterministic simulations alone or in hybrid approaches to predict broadband ground motions at the higher frequencies of engineering interest (up to and above 10 Hz). A series of simulations oriented toward that goal are those done for the 2008 M_w 5.4 Chino Hills, California, earthquake.

Olsen and Mayhew (2010) generated broadband (0–10 Hz) synthetics for the Chino Hills earthquake using a hybrid method based on the combination of low-frequency (<1.6 Hz) FD signals with high-frequency scattering operators. Olsen and Mayhew (2010) modeled the rupture as a point source with a combined strike-slip/thrust fault mechanism and used a minimum S -wave velocity of 500 m/s. Because visual

inspection was not deemed suitable for evaluation of the quality of fit between observed and synthetic data at shorter periods, Olsen and Mayhew (2010) used goodness-of-fit criteria to validate the broadband synthetics at 33 selected stations in the Los Angeles Basin. The goodness-of-fit results suggested that the threshold for acceptance was reached at two thirds of all the sites at short periods and at all the analyzed sites at moderate to long periods.

More recently, Taborda and Bielak (2013) used an entirely deterministic FE approach to model the wave propagation in the Greater Los Angeles region during the Chino Hills earthquake for frequencies up to 4 Hz and shear-wave velocities as low as 200 m/s. Their simulations used a finite source model derived from an independent inversion study and performed validations at over 300 stations between simulation synthetics and actual records. Taborda and Bielak (2013) also used a modified version of the goodness-of-fit criterion defined by Anderson (2004). Similar to Olsen and Mayhew (2010), they obtained a good agreement over the entire region at low frequencies (<0.5 Hz), but observed a decay in the goodness of fit with frequency, specially at the higher end (2–4 Hz). Their analysis indicated that this was mainly due to inaccuracies in the velocity model used (CVM-S), and in particular in the near-surface sedimentary layers, which have a stronger influence on the quality of the fit at the higher frequencies. Nonetheless, Taborda and Bielak (2013) found that the synthetics were overall realistic and concluded that future improvements to the material model will eventually render better fits. Figure 9 summarizes the results obtained by Taborda and Bielak (2013) and exemplifies the level of agreement (and lack thereof) that is possible when employing physics-based earthquake simulation to reproduce (well-constrained models of) past earthquakes.

CyberShake

The SCEC CyberShake project is an effort to develop a framework for probabilistic seismic hazard analysis that incorporates explicitly the

Physics-Based Ground-Motion Simulation, Fig. 9 Summary of results of simulation and validation of the 2008 M_w 5.4 Chino Hills earthquake. (a) Region of interest and simulation domain surface projection, (b) comparison of data and synthetics at selected locations, (c) spatial distribution of PGV interpolated from data at

recording stations, (d) spatial distribution of PGV interpolated from synthetics at the same stations, (e) bias ration between data and synthetic values of PGV, and (f) spatial distribution of the goodness-of-fit scores obtained for PGV (After Taborda and Bielak 2013)

source and wave propagation effects by means of physics-based simulations to estimate the ground motions of the expected earthquakes in a region (Graves et al. 2011). CyberShake has been initially tested for the case of the Greater Los Angeles area and will be extended to the Southern and Central California regions in the future. It consists of conducting hundreds of thousands of forward simulations for as many variations of fault ruptures as possible to consider for all active faults in the region of interest. However, in order to avoid the overload of conducting as many forward simulations as possible rupture variations for all the active faults and hypocenter locations, CyberShake precomputes strain Green tensors (SGT) between a collection of receivers (or regular grid of stations), and each of the subfault patches in each fault plane for all the finite fault models in the region. Then, CyberShake uses reciprocity to compute the synthetic seismograms for any given earthquake scenario by combining the corresponding contribution of each subfault's slip to the earthquake's finite fault model. The combined results of all the ground-motion synthetics obtained from the reciprocity computations for all the intended forward simulations offer a unique physics-based approach to the long-term seismic hazard of the region considered because the intensity measures produced by the simulations naturally incorporate 3D source, path, basin, and site effects and spatial variability of the region (as inferred from the employed velocity and source models), thus avoiding other assumptions for these effects implicitly embedded in empirical ground-motion relationships used in traditional probabilistic seismic hazard analysis. While significant further research will be required before CyberShake seismic hazard maps can be adopted in earthquake engineering analysis and design, its operational framework offers a perspective to the potential future use of physics-based earthquake ground-motion simulation.

Summary

This chapter presented the background and basic operational framework of physics-based

(deterministic) ground-motion simulation, its most commonly employed methods, and some notable recent application examples. The generation of ground-motion synthetics using a physics-based approach requires a (kinematic) finite source model and a material (seismic velocity and attenuation) model, which are used as input data for solving a forward wave propagation problem. Simulations are resolved using numerical techniques such as the finite-difference, finite-element, spectral element, or discontinuous Galerkin methods. Current uses of physics-based ground-motion simulation include the simulation of large earthquake scenarios for the assessment of the potential impact of seismic events and the evaluation of appropriate emergency management and response strategies and the construction of physics-based probabilistic seismic hazard maps (at long periods) based on local and regional fault models. Physics-based ground-motion simulation methods have been thoroughly tested through verification of scenario events and validation of small- and moderate-magnitude past earthquakes. Validation results, in particular, show that accurate seismograms (comparable to real records) can be obtained through physics-based ground-motion simulation, especially at low frequencies where both the source and the material models are better constrained. It is expected that future advances in all related areas (source models, material models, characterization of site effects, simulation methods) will permit the use of physics-based ground-motion simulations in broadband seismic hazard studies and engineering analysis and design, especially in regions where there is insufficient historical data and where simulations can complement the regional perspective of earthquake hazards.

Introduction

The most common approach to perform seismic design of structures is the traditional one based on a linear elastic analysis assumption. On the other

hand, nonlinear analysis methods due to their higher complexity and computational cost are mainly applied as a verification tool for the assessment of existing structures. The use of nonlinear analysis methods provides a robust and reliable framework for seismic design since they allow the adoption of more elaborate design criteria, based on less simplifying assumptions. For this reason the application of nonlinear analysis approaches for the seismic design of structures as discussed in detail in recent guidelines, e.g., ASCE (2007), is gaining ground among practicing engineers. This development is also attributed to the rapid increase of computing power which makes the implementation of such advance approaches more attractive for real-world applications.

Regarding finite element (FE) modeling assumptions, building structures are primarily modeled with one-dimensional beam–column finite elements (e.g., beams or rods). These models are used to represent the linear skeleton of such structures, while more detailed two- and/or three-dimensional FE models such as the ones proposed by Spiliopoulos and Lykidis 2006 are only rarely utilized. The FE structural model should also be able to adequately capture the response of other structural components that may considerably affect the overall capacity, e.g., infill walls, shear walls, and other nonstructural components. A discussion on these modeling issues can be found in the NIST 2010 document. In addition, soil–foundation–structure interaction may also play a significant role on the overall structural response. A detailed discussion on the effect of soil models of different complexity on the structural response can be found in Assimaki et al. 2012.

Considering the structural nonlinear response, there are two major sources of nonlinearity: material and geometric nonlinearity. Material nonlinearity is considered the primary source of damage for low- and medium-rise building structures, while geometrical nonlinearities should be taken into account in high-rise buildings with small aspect ratios that suffer from large horizontal deflections that introduce $P-\Delta$ effects. For the nonlinear material response, the FE simulation

with beam–column members falls into two categories: concentrated (or lumped) and distributed plasticity approach. In concentrated plasticity, also called briefly as plastic hinge approach, the plastic deformations are “lumped” at the ends of a linear elastic element and are based on the moment–rotation relationships of the end sections for a given axial force. In distributed plasticity, beam–column elements allow for the formation of plastic zones along the member, while plastic hinges may form anywhere along the member. In the latest case, the constitutive inelastic behavior is monitored at section integration points of the beam–column elements, therefore accounting for the axial–moment interaction in a straightforward manner. Several commercial software packages are available, and usually each follows a different formulation that the user/engineer must be aware in order to obtain reliable predictions of the nonlinear structural response (Fragiadakis and Papadrakakis 2008).

Material Nonlinear Approaches

Concentrated (Lumped) Plasticity Approach

Concentrated plasticity is the approach commonly suggested in most design codes and guidelines (FEMA 2009). The first concentrated plasticity beam elements were the parallel model of Clough and Johnston 1966 and the series model of Giberson (1967). Preceding developments were based on the series model aiming at including the interaction of axial force and bending moment in the form of a nonlinear rotational spring at the element ends (Fig. 1) (Powell and Chen 1986). Further developments on lumped plasticity elements were focused on the implementation of cyclic laws. Models that introduce cyclic stiffness degradation and pinching have been proposed. Such models either modify the path of the reloading branch (Clough and Johnston 1966) or introduce “pinching” (Ibarra et al. 2005). Apart from linear or piecewise linear models, smooth hysteretic models have also been developed (Wen 1976) in order to provide a continuous change of stiffness for the nonlinear springs. Huang and Foutch (2009)

Plastic Hinge and Plastic Zone Seismic Analysis of Frames, Fig. 1 Lumped plasticity model of a portal frame: three beam–column FE and four rotational springs

performed a comparative study investigating the effect of different cyclic laws. An efficient beam–column element is also the force-based lumped plasticity element proposed in Scott and Fenves (2006). This approach combines the benefits of concentrated and distributed plasticity elements since it uses a minimum number of integration sections maintaining all the advantages of force-based distributed plasticity elements which are discussed in the next section.

In lumped plasticity approaches, the constitutive laws are expressed in terms of stress resultants (i.e., moment–rotations). This allows for the adoption of more complex phenomenological relationships with respect to distributed plasticity elements in which direct constitutive stress–strain relationships are used instead. In addition, lumped plasticity beam–column elements are more robust and reduce the computational cost and the memory requirements. This allows simulating complicated responses provided that the springs are appropriately calibrated. However, the concentrated plasticity approach relies on simplifying assumptions, restricting the inelastic deformations to prespecified regions of small length. Furthermore, there is no axial–moment interaction, and thus the springs are calibrated assuming constant axial force during dynamic analysis. Keeping constant the properties of the springs during analysis is another restriction of this modeling approach. Anagnostopoulos (1981) presented a parametric investigation showing that under monotonic loading the response is very sensitive

to the parameters of the springs, while Dides and de la Llera (2005) showed that for typical multistory structures, the response is influenced by the ratio of the beam-to-column stiffness. It has to be mentioned that such models usually lead to better response estimates for steel (Papadrakakis and Papadopoulos 1995) rather than for concrete structures. Prior to adopting lumped plasticity modeling, one must also be aware of the inability of lumped plasticity to capture the response under softening behavior (e.g., reinforced concrete structures).

End Section Moment–Rotation

As mentioned above, lumped plasticity elements receive as input the moment–rotation relationships of the cross sections of interest, assuming that it is already known. The section moment–rotation ($M-\theta$) relationship can be defined assuming a backbone whose parameters are determined combining first principles and default values or performing section (fiber) analysis with appropriate software. This backbone is discussed in the FEMA P695 (2009) guidelines and is shown in Fig. 2. As shown in this figure, the curve essentially consists of three branches, an initial elastic (K_e), a hardening branch (K_h) and a descending branch with slope K_c that is used to introduce degradation. Degradation can be either “in-cycle,” i.e., defined with a negative stiffness branch and, or “cyclic.” Cyclic degradation usually refers to strength degradation (but not exclusively) at given displacement cycles due to capacity reduction during cyclic loading.

The sensitivity of a building's response to the parameters that define the backbone is demonstrated in Vamvatsikos and Fragiadakis (2010), while a comprehensive discussion on cyclic and in-cycle degradation is also offered in NIST (2010) document.

Distributed Plasticity Approach

Distributed plasticity beam-column elements offer a more accurate description of the inelastic behavior since they allow inelastic deformations to be developed anywhere within the member. These elements are also known as “fiber”

Plastic Hinge and Plastic Zone Seismic Analysis of Frames, Fig. 2 Discretization of an arbitrary cross section to fibers

elements, since the sections are divided to horizontal and vertical layers forming small areas, known as “fibers,” where the strain and stiffness parameters are evaluated (Fig. 3). Fiber elements are based on the classical FE theory with cubic Hermitian shape functions (Hellesland and Scordelis 1981). These elements are known in the literature as “displacement-based” or “stiffness-based” elements, and their shortcoming is that they require a fine mesh of beam-column elements in areas near the sections in which inelastic deformations are expected to be high (Fig. 4a). This is because the cubic shape function assumption leads to a linear distribution of the curvature along the element, which is inaccurate when the element end sections have yielded.

To overcome the problem stemming from the unknown distribution of curvature along the element, flexibility-dependent shape functions can be used instead (Fig. 3b). In this case, it is the distribution of forces (moments) that matters, while the element stiffness matrix can be easily calculated by summing the section flexibility matrices and inverting the resulting element flexibility matrix. This concept was extended by Kaba and Mahin (1984) and later was improved by Zeris and Mahin (1988) and Ciampi and Carlesimo (1986). These elements assume that the element is divided to equally spaced sections that allow the element to produce accurate predictions in the case of softening behavior, or in other words when the post-yield deformation path enters a segment with negative slope (softening). This formulation is also known as

Plastic Hinge and Plastic Zone Seismic Analysis of Frames, Fig. 3 Typical moment-rotation curve according to FEMA P695 (2009)

Plastic Hinge and Plastic Zone Seismic Analysis of Frames, Fig. 4 Modeling a portal frame using (a) displacement-based and (b) force-based elements

“force-based” or “flexibility-based.” Following the previous concept, Spacone et al. (1996) introduced a general mixed-type, fiber-based, beam–column element. At the integration sections, this element always maintains equilibrium of both forces and deformations and converges to a state that satisfies the constitutive laws within a specified tolerance.

Compared to lumped plasticity, the main shortcoming of distributed plasticity elements is that they require more computing resources. Numerical instabilities may be encountered if criteria that introduce abrupt loss of capacity are adopted, e.g., when trying to predict collapse. On the other hand, distributed plasticity elements do not require any special calibration and can be easily adopted for sections that consist of different materials since they use stress–strain relationships suitable for each fiber material. A discussion on distributed plasticity elements can be found in Neuenhofer and Filippou (1997), while comparisons between the force

and the displacement-based elements are presented in Neuenhofer and Filippou (1997) and Papaioannou et al. (2005). All studies converge that this formulation is accurate and robust and therefore suitable for a wide range of applications. A concise review on concentrated and distributed plasticity approaches can be found in Fragiadakis et al. (2015).

Section/Member Level

Fiber elements differ from lumped plasticity elements in the sense that they perform the integration over the fibers internally and therefore receive as input the parameters that define the stress–strain relationships of their fibers. On the other hand, lumped plasticity elements receive as input the moment–rotation relationships of the cross sections of interest, assuming that it is already known. In both cases, estimating the inelastic response requires integrating the stresses calculated at appropriately selected cross sections. Therefore, it is essential to be able to sufficiently capture the moment–rotation relationship of a cross section of a given geometry and reinforcement. Numerically, moment–rotation relationships are obtained using the fiber approach, i.e., discretizing the cross section to fibers that each follows its own material law.

Example

The simple example of the 1-story, 1-bay moment frame of Fig. 1 is modeled with wide-flange steel sections. The frame’s bay width and height are set to 4 m. The beam and columns of the steel frame are standard HEB 220 sections. For the distributed plasticity model, each section is divided into fibers where elastic perfectly plastic material with a yield stress $\sigma_y = 355$ MPa is assigned independently to each fiber. As shown in Fig. 5, the flanges and the web of the HEB 220 cross section are discretized into 64 fibers. For the concentrated plasticity model, the frame is modeled using a beam with hinge elements represented by rotational springs at the element end. The backbone curve describing the nonlinear behavior of the springs is calculated by integrating strains across the section (Fig. 5) and is presented in Fig. 6.

Plastic Hinge and Plastic Zone Seismic Analysis of Frames,

Fig. 5 Discretization of HEB 220 section to fibers

Plastic Hinge and Plastic Zone Seismic Analysis of Frames, Fig. 6 Backbone

curve of a HEB 220 steel section

Figure 7a and b presents the pushover curves for both concentrated and distributed plasticity models and the corresponding incremental dynamic analyses (IDA), respectively. For the pushover analysis, the structure is pushed to a maximum 10 % roof drift. For the IDA case, the structural model is subjected to Canoga Park record from the 1994 Northridge earthquake scaled to multiple levels of intensity. The IDA curves of Fig. 7b plot an engineering demand parameter (EDP), in this case

the maximum interstory drift $\theta_{\max}$, as a function of the earthquake intensity measure (IM) which is selected to be the maximum ground motion acceleration (PGA). From these figures the small difference on the structural response obtained by the two different models may be observed.

Summary

A critical review of the current state of the art of the computing practices adopted by the

Plastic Hinge and Plastic Zone Seismic Analysis of Frames,

Fig. 7 Comparison of (a) pushover and (b) IDA curves obtained with lumped and distributed plasticity models

earthquake engineering community is presented. The presentation extends from the finite element modeling of earthquake-resistant structures and the analysis procedures currently used to account for material nonlinearity. The two most commonly used approaches, namely, the plastic hinge and plastic zone approach, for estimating the structural capacity of seismically excited structures are discussed, and their relative advantages and disadvantages are presented together with the various aspects, developments, and implementations of these approaches over the past years. A comparison of the two approaches is presented in a simple example for both static pushover and incremental dynamic analysis approaches.

Damage detection; Instrumented buildings; Post-earthquake diagnosis; Structural dynamics; Wave propagation

Introduction

Post-earthquake diagnosis of building structures is essential in order to determine if a building can be safely re-occupied after a potentially damaging seismic event. The most traditional methodology is the use of visual inspections (ATC-20 2005). These inspections are made by qualified professionals and can take from a few days to possibly months. The effectiveness of the inspection will depend on a large part on the experience

of the inspector and accessibility to the structural damage. This last aspect was clearly manifested during the 1994 Northridge earthquake where hidden structural damage in buildings was not detected by qualified inspectors. Recently, researchers have begun to look at methods that rely on computer vision to perform the visual assessment in an automated fashion (German 2013). In principle this approach also relies on the damage being visible.

In the context of post-earthquake damage assessment, the term damage should be interpreted as reduction in stiffness and/or strength of any member in the structural system of the building. The loss of stiffness or strength can occur due to a single occurrence of a maximum relative displacement (drift) or due to short-cycle fatigue induced by alternating displacements that are characteristic of earthquake-induced ground motion. Depending on the type of material used for the building structure, visual symptoms of damage may or may not exist. On the other hand, visual symptoms do not necessarily imply that significant damage has occurred. For example, in reinforced concrete buildings, cracks may appear after a strong ground motion; however, this does not imply a reduction in strength. Due to the shortcomings with visual inspections, vibration-based post-earthquake assessment has been proposed.

Vibration-based post-earthquake damage assessment uses acceleration from the building response measured through accelerometers to detect, localize, and quantify the damage experienced by the building during the seismic event. Ideally, a building would be instrumented with six accelerometers per floor in order to capture the six possible independent motions of the floor (assuming rigid floor diaphragm). However, in most cases instrumentation can only take place at a limited number of locations, typically significantly less than the ideal number. The scientific challenge in vibration-based post-earthquake damage assessment is to develop algorithms that can use all available information (such as structural drawings, previous history of measured seismic events in the building, construction

information, etc.) together with limited acceleration measurements during the potentially damaging ground motion in order to perform the correct diagnosis.

Various algorithms have been proposed to perform post-earthquake diagnosis (Moaveni et al. 2011; Todorovska and Trifunac 2010; Bernal and Hernandez 2006; Lynch et al. 2006; Naeim et al. 2005; Revadigar and Mau 1999; Mau and Aruna 1994). Based on the relationship between the window(s) of time used to perform the diagnosis and the time of occurrence of the seismic event, existing methods can be broadly classified into “before-and-after” or “on-line” methods. As the name suggests, in the “before-and-after” strategy, the objective is to make a diagnosis based on measurements of the structural response prior to the potentially damaging event and measurements after the event, typically ambient vibrations. In the “on-line” strategy, the objective is to use the data during the seismic event to make the diagnosis.

Depending on the feature that is selected to characterize damage and on the definition of damage itself, existing methods can be broadly classified into:

- Spectral
- State estimation
- Wave propagation
- Energy methods
- Time series
- Model updating

As the name suggests, spectral methods search for changes in the spectral parameters of the structure (mode shapes and frequencies). Since damage is typically related to the loss of effective stiffness and modal parameters are directly related to the stiffness characteristics of the structure, it is intuitive to use these as a damage indicator. In this approach damage detection involves processing of acceleration records to determine changes in the frequency content of the measured acceleration using sliding windows Fourier analysis or time–frequency methods (Naeim et al. 2005; Todorovska and Trifunac 2010;

Moaveni et al. 2011; Asgariéh et al. 2012). If the effective frequency decreases during the strong motion window of time, then one would tend to infer that the stiffness of the system has decreased and structural damage has occurred.

State estimation methods operate by using partial measurements as feedback in order to estimate the complete dynamic response of the system and possibly track changes in the parameters of the model. Typically, some form of Bayesian filtering is used to perform the estimation (Chatzis et al. 2015). Damage features can be related to estimated functions of the state such as maximum drifts and/or damage indices (Erazo 2015; Hernandez and Erazo 2013). Alternatively, if changes in model parameters are used for damage assessment, then these need to be included in the state vector and estimated jointly with the traditional system state (Ching et al. 2006; Chatzi and Smyth 2009).

Another feature that has been proposed to detect damage in buildings is tracking seismic wave propagation through the building (Safak 1999). Wave propagation parameters include wave travel time between the floors and wave reflection and transmission coefficients of the floors. These have shown to be more sensitive to local damage than natural frequencies and provide yet another set of criteria for damage detection. However, the calculation of wave propagation parameters requires a dense array of sensor and recorders with a high rate of sampling. With the present sensor technology, the associated cost of the required level of instrumentation density may not be viable in all cases.

In energy methods the damage detection feature is the dissipated energy ratio which is a function of the energy dissipated by damping and the total energy dissipated. As mentioned previously and in contrast with existing methods previously described, dissipated energy is not an intrinsic property of linear systems and can be computed independent of whether the system is operating under linear or nonlinear range. In addition, the proposed damage feature has a very clear physical meaning and is by definition intimately related to earthquake-induced damage

of engineered structures (Uang and Bertero 1990; Sucuoglu and Erberik 2004; Teran-Gilmore and Jirsa 2007).

Time series methods have also been proposed. This family of methods relies on changes in the time history response or in the identified black-box input–output model coefficients. Lynch et al. (2006) developed a wireless sensor network system and used residuals generated from AR-ARX models as a damage-sensitive feature. The algorithm is based on the work of Sohn and Farrar (2001). Bernal and Hernandez (2006) developed a signal-processing algorithm based on the cumulative integral of residuals from partial ARX models. The partial ARX models are identified from non-damaging events and subsequently used to estimate the expected linear response of the building during the event of interest. The rate of accumulation of the cumulative integral of the residual between the partial ARX prediction and the measured response is used as a damage detection and classification feature.

The time series methods have the advantage (which can also be viewed as a disadvantage in some cases) of working with almost no information from a structural model of the system and relying completely on identified black-box models from measured data. This reduces the sensitivity to structural modeling errors, but the analysis is based entirely on numerical features not easily relatable to physical quantities pertinent to the problem. This makes time series methods less appealing since it is difficult to correlate the results with structural quantities of interest (such as forces, moments, drifts, etc.) related to structural damage.

Finally, model updating methods operate by identifying changes in the parameters of models formulated based on structural mechanics principles. Typically, these parameters are related to stiffness properties of the structural members of the model (beams, columns, walls, etc.). Model updating methods can operate within the “before-and-after” or “on-line” strategy. In the “before-and-after” strategy, the model parameters identified from ambient vibration before the ground motion or simply selected from experience are compared with the model parameters identified

from ambient vibrations after the ground motions (Simoen et al. 2015). If a significant change (or probability of change) is detected, then structural damage is deemed to have taken place. In the “on-line” strategy, as the name suggests, the model parameters are identified using the measured response during the ground motion (Ching et al. 2006; Chatzi and Smyth 2009). In this case, a more detailed evaluation can be conducted since in addition to stiffness parameters, hysteretic damage parameters can also be identified (which is not possible in the “before-and-after” strategy). Hysteretic behavior is known to be highly correlated to low-cycle fatigue damage typically experienced by buildings during strong earthquakes.

After this brief description of the various methodologies, a more detailed description of some of the methods is presented in the following sections.

Spectral Methods

Spectral methods operate under the assumption that the dynamic response of a building before and after the strong ground motion is governed by the following linear equation of motion:

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = r\ddot{u}_g(t) \quad (1)$$

where $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the mass, damping, and stiffness matrices of size $n \times n$. The response vector is $\mathbf{x}(t)$, $u_g(t)$ is the ground motion, and r is the ground motion influence vector. The corresponding undamped eigenvalue problem is

$$\mathbf{M}\phi_i\omega_i = \mathbf{K}\phi_i \quad (2)$$

where ω_i is the circular frequency of the i th mode and ϕ_i is the corresponding undamped mode shape. Spectral methods operate by interrogating changes in the mode shapes and frequencies before and after the ground motion, although more recently, data during the ground motion has been also used to identify the “changing” natural frequencies of the system as a sign of damage. The general assumption is that damage

induces reduction in stiffness, and reduction in stiffness is reflected in a reduction in the frequencies of the structure.

Challenges with the spectral methods include the following: (i) the intrinsic global nature of the modal properties makes it challenging (although not impossible) to point to the location of the damage; (ii) there are factors other than damage that produce similar effects on the damage-sensitive features, which are not easy to isolate (the effects of soil–structure interaction on the measured frequencies of vibration and environmental influences such as temperature); and (iii) only low-frequency modes can be reliably identified from vibration data in buildings, and these frequencies have low sensitivity to local damage.

State Estimation Methods

In state estimation methods, as the name suggests, the objective is to estimate the complete dynamic response (state) based on a model of the system and noise-contaminated partial measurements. For application in post-earthquake assessment, state estimation methods have been applied in two different avenues: (1) by using acceleration measurements to estimate the complete dynamic response, including displacements, velocities, interstory drifts, interstory shears, and overturning moments (the estimated quantities can be compared with structural capacity values of structural elements) (Mau and Aruna 1994; Hernandez and Bernal 2008), and (2) enlarging the state to include model parameters and identifying the model parameters (Ching et al. 2006). By identifying changes in model parameters, one can infer damage.

The nonlinear response during a strong ground motion can be modeled as

$$\mathbf{M}\ddot{\mathbf{x}}(t) + g_R(x, \dot{x}, \theta) = r\ddot{u}_g(t) \quad (3)$$

where g_R is a restoring force function, typically hysteretic. The restoring force function is defined by a set of parameter which we denote as θ .

By defining the state vector as $z^T = \{x^T \dot{x}^T \theta\}$, the equation of motion can be rewritten in first-order (state–space) form as

$$\dot{z}(t) = f(z(t)) + \mathbf{B}\ddot{u}_g \quad (4)$$

Measurements of the building response can be represented as function of the state as

$$y(t) = h(z(t)) + v(t) \quad (5)$$

where $v(t)$ is the measurement noise, typically small but not negligible during strong motions. The objective in state estimation methods, as the name suggests, is to estimate the complete state vector from noise-contaminated measurements $y(t)$. State estimation methods constitute an application of Bayes theorem:

$$p(z(t)|Y) = \frac{p(Y|z(t))p(z(t))}{p(Y)} \quad (6)$$

where $Y(t) = y([0 \ t])$. If the model is linear, then the application of Bayes theorem results in the Kalman filter (Grewal and Andrews 2001). If the model is nonlinear, several extensions of the Kalman filter have been proposed. Among these methods, the most popular ones are the extended Kalman filter, unscented Kalman filter, ensemble Kalman filter, and the particle filter (Sarkka 2013).

Wave Propagation Methods

This method uses data from acceleration sensors to detect changes in structural stiffness based on the analysis of travel times of seismic waves propagating through the structure (Todorovska and Trifunac 2007, 2010). The physical basis for this approach is based on the one-dimensional shear-wave propagation velocity:

$$V_s = \sqrt{\frac{\mu}{\rho}} \quad (7)$$

where μ is the shear stiffness and ρ is the density. Changes in the shear stiffness (due to damage) will result in a reduction in wave velocity and

consequently an increase in travel time between sensors. Wave propagation methods are more sensitive to local damage than the modal methods and should be able to point out to the location of damage with relatively small number of sensors. Additionally, the local changes in travel time should not be sensitive to the effects of soil–structure interaction, which is a major obstacle for the modal methods.

The spatial resolution of the wave methods is limited by the number of sensors. A minimum of two sensors (at the base and at the roof) are required to determine if the structure has been damaged, and additional sensors at the intermediate floors would help point out to the part of the structure that has been damaged. For example, one additional sensor between these two would help identify if the damage has been in the part of the structure above or beyond that sensor.

Energy Methods

Energy methods are based on identifying dissipated energy. Dissipated energy has a very clear physical meaning and is by definition intimately related to earthquake-induced damage of engineered structures (Uang and Bertero 1990; Sucuoglu and Erberik 2004; Teran-Gilmore and Jirsa 2007; Jehel et al. 2008).

To illustrate the concept, consider the governing equation of motion for an SDOF oscillator with viscous damping subject to a base motion time history $x_g(t)$:

$$m\ddot{y} + c\dot{x} + kx = 0 \quad (8)$$

where m is the mass, c is the viscous damping coefficient, and k is the stiffness coefficient. The absolute acceleration of the mass is $\ddot{y} = \ddot{x} + \ddot{x}_g$, and the relative displacement and velocity are x and $\dot{x}$, respectively. To obtain the energy balance relationship, we multiply both sides of the equation by $\frac{dx}{dt} dt$ and integrate between arbitrary time t_1 and t_2 :

$$m \int_{t_1}^{t_2} \ddot{y} \dot{x} dt + c \int_{t_1}^{t_2} \dot{x}^2 dt + k \int_{t_1}^{t_2} x \dot{x} dt = 0 \quad (9)$$

The third term in the left-hand side is the elastic strain energy stored between t_1 and t_2 :

$$\begin{aligned} \int_{t_1}^{t_2} kx \dot{x} dt &= \int_{t_1}^{t_2} kx \frac{dx}{dt} dt = \int_{x(t_1)}^{x(t_2)} kx dx \\ &= U = \frac{1}{2} kx^2 \Big|_{x(t_1)}^{x(t_2)} \end{aligned} \quad (10)$$

Therefore, in the limit, if the system starts from rest at t_1 and we let t_2 go to infinity until the system returns to its static equilibrium point, the strain energy integral U vanishes, and the dissipated energy (E_D) converges to the energy dissipated by viscous damping (E_{damp}), namely,

$$E_D = E_{\text{damp}} = c \int_0^\infty \dot{x}^2 dt = -m \int_0^\infty \ddot{y} \dot{x} dt \quad (11)$$

For a nonlinear system with hysteretic restoring force relationship, the integral in Eq. 2 is modified to incorporate the dissipated energy through hysteresis loops, resulting in

$$m \int_{t_1}^{t_2} \ddot{y} \dot{x} dt + c \int_{t_1}^{t_2} \dot{x}^2 dt + \int_{t_1}^{t_2} f_R \dot{x} dt = 0 \quad (12)$$

where f_R is the restoring force function. If the system starts from rest at $t_1 = 0$ and we let t_2 go to infinity until the system returns to one of its equilibrium points, the total energy dissipated by the system is given by

$$\begin{aligned} E_D &= c \int_0^\infty \dot{x}^2 dt + \int_0^\infty f_R \dot{x} dt = E_{\text{damp}} + E_h \\ &= -m \int_0^\infty \ddot{y} \dot{x} dt \end{aligned} \quad (13)$$

As can be seen, the expression for total dissipated energy, for linear (Eq. 4) and nonlinear (Eq. 6) hysteretic systems, is exactly the same. This invariance property makes the use of energy as a damage detection feature appealing. The expression for total dissipated energy by hysteresis is found from Eq. 6 as

$$E_h = \int_0^\infty f_R(x, \dot{x}) \dot{x} dt = -m \int_0^\infty \ddot{y} \dot{x} dt - c \int_0^\infty \dot{x}^2 dt \quad (14)$$

Based on the previous analysis, Hernandez and May (2013) proposed the following damage index (Z), defined for an SDOF as

$$Z = \frac{E_h}{E_D} = 1 - \frac{E_{\text{damp}}}{E_D} = 1 + \left(\frac{c}{m} \right) \frac{\int_0^{t_r} \dot{x}^2 dt}{\int_0^{t_r} \ddot{y} \dot{x} dt} \quad (15)$$

Other energy-based approaches that have been proposed rely on the identification of viscous damping (Satake et al. 2003). In these approaches, the premise is that effective viscous damping increases with damage. This is due to cracking, yielding, and other damage-related phenomena which results in higher levels of dissipated energy. The main drawback of this approach is that damping is difficult to identify accurately and its variability is high.

Time Series

Time series methods operate by identifying ARMA models of the form

$$\sum_{k=0}^l A_k y(p-k) = \sum_{k=0}^n B_k u(p-k) \quad (16)$$

where $A_k \in R^{m \times m}$ and $B_k \in R^{m \times p}$ are matrices, $y(h)$ is the measurement vector at time $t = h \Delta t$, and similarly $u(h)$ is the ground motion vector at time $t = h \Delta t$. To detect damage, time series methods search for changes in identified matrices A_k and B_k and(or) by examining the residuals between measurements during the ground motion and predictions provided by an ARMA model identified prior to the occurrence of the ground motion of interest. The residuals are defined as

$$\varepsilon(t) = y_m(t) - y(t) \quad (17)$$

where y_m is the measured acceleration and y is the model prediction. Bernal and Hernandez (2006) proposed two scalars, η and κ , where η measures the total extent of nonlinearity and κ captures the degree to which the structure recuperates the initial stiffness after the strong portion of the earthquake excitation is over. These metrics are computed as follows:

$$\gamma(t) = \frac{\int_0^t \varepsilon^2 dt}{\int_0^{t_{\max}} y_m^2 dt} \quad (18)$$

where

$$\eta = \gamma_{t=t_{\max}} \Big|_{\max \text{ over all channels}} \quad (19)$$

and

$$\kappa = \frac{S_e}{S_r} \Big|_{\max \text{ over all channels}} \quad (20)$$

where $t_{\max}$ = total duration of the earthquake record. It is implicit that Eq. 18 can be computed for every output channel and that the superscript t has been eliminated from the variables to simplify the notation. The numerator in Eq. 20 is the average slope of the curve given by Eq. 18 computed after it reaches 95 % of its final value, and the denominator is the slope of a line joining the 10 % to the 90 % values of the function in Eq. 18 for the earthquake used to identify the ARMA model. Various limits where proposed by Bernal and Hernandez (2006) on the constants γ and κ in order to separate undamaged buildings from potentially damaged ones. One drawback of this approach resides in the fact that residuals between building response and identified model predictions can occur due to many factors not related to damage, such as changes in building boundary conditions.

Model Updating

Model updating methods operate by identifying changes in the parameters (θ) of models formulated based on structural mechanics principles.

Typically, these parameters are related to stiffness properties of the structural members of the model (beams, columns, walls, etc.). Model updating methods can operate within the “before-and-after” or “on-line” strategy. In the “before-and-after” strategy, the model parameters identified from ambient vibration before the ground motion or simply selected from experience are compared with the model parameters identified from ambient vibrations after the ground motions (Simoen et al. 2015). If a significant change (or probability of change) is detected, then structural damage is deemed to have taken place. If a Bayesian approach is used, then the joint probability of the parameters given measurements is given by

$$p(\theta|Y_B) \propto p(Y_B|z\theta)p(\theta) \quad (21)$$

$$p(\theta|Y_A) \propto p(Y_A|z\theta)p(\theta) \quad (22)$$

where Y_B and Y_A are sets of ambient response measurements before and after the ground motion, respectively. More details regarding identification and model updating using ambient vibration can be found in Simoen et al. (2015). Damage is typically assessed by contrasting the two probability densities $p(\theta|Y_B)$ and $p(\theta|Y_A)$ or more simply by looking for shifts in the maximum likelihood value of these distributions (if they are unimodal).

In the “on-line” model updating strategy, as the name suggests, the model parameters are identified using the measured response during the ground motion (Ching et al. 2006; Chatzi and Smyth 2009). In this case, a more detailed evaluation can be conducted since in addition to stiffness parameters, hysteretic damage parameters can also be identified (which is not possible in the “before-and-after” strategy). Hysteretic behavior is known to be highly correlated to low-cycle fatigue damage typically experienced by buildings during strong earthquakes. Most of the work found in the literature uses shear building models and Bouc–Wen models (Bouc 1971) to represent the interstory restoring force function. The main drawback of model updating methods is their lack of robustness to model

errors (especially model class errors); this has been clearly illustrated in Ching et al. (2006). It is recommended that when using model updating methods, careful selection of the model class be exercised. In addition if the free parameter space is too large, uniqueness problems are to be expected; thus, the user needs to have good a priori knowledge of which elements are likely to exhibit damage and which ones not, thus excluding unnecessary parameters from the updating procedure.

Summary

Post-earthquake diagnosis of building structures is essential in order to determine if a building can be safely re-occupied after a potentially damaging seismic event. The most traditional methodology is the use of visual inspections. Depending on the type of material used for the building structure, visual symptoms of damage may or may not exist. Due to the shortcomings with visual inspections, vibration-based post-earthquake assessment has been proposed, developed, and implemented during the last few decades.

Vibration-based post-earthquake damage assessment uses acceleration from the building response measured through accelerometers to detect, localize, and quantify the damage experienced by the building during the seismic event. Various algorithms have been proposed to perform post-earthquake diagnosis. Existing methods for post-earthquake damage assessment can be broadly classified into spectral, state estimation, wave propagation, time series, energy methods, and model updating. This entry presents a summary of each method, their pros and cons, and range of applicability.

Principles of Broadband Seismometry

Nick Ackerley

Nanometrics, Inc, Kanata, Ottawa, ON, Canada

Synonyms

Weak-motion sensor; Very broadband seismometer

Introduction

There are many different types of instruments which can be used to detect ground motion. Broadband seismometers belong to a class of sensors called inertial sensors. In contrast, methods of sensing ground motion such as strainmeters and Global Positioning Systems (GPS) are not considered inertial sensors.

In this entry the principles of operation of broadband seismometers are discussed and contrasted with those of passive seismometers. The criteria for selecting a seismometer are discussed. Particular attention is paid to noise-generating mechanisms, including self-noise generated within the sensor, environmental sensitivities, and installation-related noise.

Applications

Broadband seismometers are very versatile instruments which have many applications in the field of earthquake engineering, including:

- Event detection and location (see ► [Seismic Event Detection](#) and ► [Earthquake Location](#))
- Earthquake magnitude and moment-tensor estimation (see ► [Earthquake Magnitude Estimation](#), ► [Earthquake Mechanism Description and Inversion](#) and ► [Long-Period Moment-Tensor Inversion: The Global CMT Project](#))
- Volcanic eruption early warning (see ► [Volcanic Eruptions, Real-Time Forecasting of](#))

and ► [Noise-Based Seismic Imaging and Monitoring of Volcanoes](#))

- Subsurface imaging
- Site response (see, e.g., ► [Site Response: Comparison Between Theory and Observation](#) and ► [Site Response for Seismic Hazard Assessment](#))
- Restitution of ground displacement (see ► [Selection of Ground Motions for Response History Analysis](#) and ► [Seismic Actions due to Near-Fault Ground Motion](#))

Classes of Inertial Sensors

In the broadest sense, a seismometer is any instrument which responds to ground motion, and a seismograph is any instrument which subsequently makes a recording of that ground motion. In practical usage however, a seismometer refers to a specific subclass of inertial sensors. One way to understand where the broadband seismometer is situated relative to the other classes of instruments, which measure ground motion, is to take a tour of the family tree of inertial sensors.

Inertial sensors consist of a frame and a “proof mass” suspended within the frame. Movement of the frame is sensed by sensing differential motion between the frame and the proof mass. The suspension usually constrains the proof mass to have one or more degrees of freedom, which can be either rotational or translational. If these degrees of freedom are purely rotational, the instrument is called a rotational seismometer or a gyroscope (see Lee et al. 2012).

Translational inertial sensors have many subclasses. One way of understanding their classification is to look primarily at the types of motion each is designed to measure: static or dynamic, strong or weak, horizontal or vertical, and long period or short period (these terms are explained in the paragraphs which follow).

Inertial sensors which are configured to detect static accelerations include gravimeters and tiltmeters, which are arranged to detect vertical and horizontal accelerations, respectively. Neither instrument is required to measure the full acceleration due to gravity. A tiltmeter can be leveled to produce zero output when it is installed; the mainspring of a gravimeter is

similarly adjusted to cancel a standard acceleration due to gravity. Thus the sensitivity of a gravimeter or a tiltmeter can be quite high because the range of accelerations to be measured is quite small. Finally, since traveling seismic waves are generally not of interest for gravimeters and tiltmeters, these instruments typically have a low-pass characteristic with an upper corner frequency which is relatively low, typically 1 Hz or lower.

An ► [accelerometer](#) is another type of inertial sensor which is configured to detect accelerations down to zero frequency. Unlike a gravimeter or a tiltmeter, they are typically configured to read peak accelerations on the order of 1 g or larger without clipping and thus must have relatively low sensitivities. They can be used to detect static accelerations, for the purpose of integrating them to obtain position as in an inertial guidance system, or they can be used to detect strong seismic motions. Like a gravimeter they have a flat response to acceleration down to zero frequency, but the upper corner of their low-pass response will be at a much higher frequency.

A seismometer differs from gravimeters, tiltmeters, and accelerometers in that it is not required to respond to ground motion all the way down to zero frequency; this enables it to have a higher sensitivity and therefore measure much smaller motions than an accelerometer. They typically have transfer functions which are flat to velocity over at least a decade, but many hybrid responses, flat to acceleration over some significant band, are viable alternatives (Wielandt and Streckeisen 1982). “Strong-motion velocity meters” capable of detecting motions as large as those detectable on an accelerometer are also commercially available, but the term seismometer is generally reserved for an instrument which measures weak motion.

Traditionally the basic subgroupings of seismometers were long period or short period, depending on whether the lower corner period is above or below about 7 s period (see section “[Ground Motion Spectra](#)” below). Modern broadband seismometers span both frequency bands and have made long-period seismometers obsolete.

Principles of Broadband Seismometry,

Fig. 1 Response to acceleration of inertial sensors

Principles of Broadband Seismometry,

Fig. 2 Response to velocity of inertial sensors

Like a short-period seismometer, a geophone is usually a passive seismometer (see ► [Historical Seismometer](#) and ► [Passive Seismometers](#)), but one with a higher corner frequency and lower sensitivity.

The transfer functions of representative examples from the main classes of inertial sensors are plotted in Fig. 1 for ground motion in units of acceleration and in Fig. 2 for units of velocity. Seismometers have the highest sensitivity of all inertial seismometers, and broadband seismometers

have the highest sensitivity of all of these classes at long periods, but not at zero frequency.

The following sensors were taken as typical of the classes shown in Figs. 1 and 2:

- **Accelerometer:** a class A accelerometer (Working Group on Instrumentation, Siting, Installation, and Site Metadata 2008), e.g., Nanometrics Titan
- **Gravimeter:** based on the CG-5 (Scintrex Limited 2007)

- **Broadband seismometer:** based on the Trillium 120 (Nanometrics, Inc 2009)
- **Short-period seismometer:** based on the S-13 (Geotech Instruments, LLC 2001)
- **Geophone:** based on the SG-10 (Sercel - France 2012)

For more discussion of the importance of the sensitivity of a seismometer to its performance, see section “[Response](#).”

Force Feedback

The principles of operation, benefits, and drawbacks of an active inertial sensor are best understood in relation to the operation of a passive inertial sensor, since the latter is effectively a component in the former.

Modern short-period seismometers and geophones are passive inertial sensors which consist of a pendulum with a velocity transducer with sensitivity G in $\text{V}\cdot\text{s}/\text{m}$ mounted so as to measure the relative velocity $\dot{x}_b$ of a proof mass M and frame of the sensor, as shown in Fig. 3. The spring constant of the mainspring and suspension combined K and the viscous damping B determine the transfer function of the pendulum, required to relate the output voltage v_o to the input motion of the frame, $\dot{x}_i$.

A block diagram of the whole passive seismometer system, from ground motion to the digitizer, is shown in Fig. 4.

The Laplace transform of the transfer function which converts frame velocity to an output voltage is (Aki and Richards 2002; Wielandt 2002)

$$\frac{V_o}{sX_i} = G \frac{s^2}{s^2 + \frac{B}{M}s + \frac{K}{M}} \left[\frac{\text{V}\cdot\text{s}}{\text{m}} \right]$$

Here the output voltage V_o and input displacement X_i are written in uppercase to emphasize that this transfer function operates in the frequency domain. It is a property of the Laplace transform that multiplication by the (complex) frequency s in the frequency domain is equivalent to differentiation in the time domain, so sX_i is the input *velocity*. Another property of the Laplace transform is that to evaluate the (complex) transfer function at a given frequency f in Hz or angular frequency $\omega = 2\pi f$ in rad/s, one makes the substitution $s = j\omega$.

For high sensitivity in the passband, the generator constant of the velocity transducer must be large. Typically the velocity transducer is constructed like a voice coil in a speaker: many turns of copper passing through a narrow gap in a magnetic circuit energized by a strong magnet

Principles of Broadband Seismometry, Fig. 3 Mechanical schematic of a passive inertial sensor

Principles of Broadband Seismometry,

Fig. 4 System block diagram of a passive inertial sensor

with large diameter are required for a large generator constant. This is shown schematically in Fig. 3.

By comparison with the standard form of a second-order transfer function

$$F(s) = S \frac{s^2}{s^2 + 2\zeta_0 \omega_0 s + \omega_0^2}, \quad (1)$$

we can write expressions for the sensitivity S , the natural frequency f_o in Hz, the angular natural frequency $\omega_0 = 2\pi f_o$, and the (dimensionless) damping constant ζ_0 of the pendulum:

$$S = G$$

$$f_o = \frac{\omega_0}{2\pi} = \frac{1}{2\pi} \sqrt{\frac{K}{M}}$$

$$\zeta_0 = \frac{1}{2\omega_0} \frac{B}{M} = \frac{B}{2\sqrt{KM}}$$

Below the natural frequency, the sensitivity of passive seismometer drops off rapidly, as shown in Figs. 1 and 2. At the resonant frequency, the degree of “peaking” in the transfer function is controlled by the damping constant ζ_0 . Low damping corresponds to a strongly peaked response, something which is generally not desirable, because it means the output will be dominated by signal at that frequency, and because the system has a greater tendency to clip at that frequency.

For high sensitivity at low frequencies, the spring stiffness K [N/m] must be low and the mass M [kg] must be large. For maximum bandwidth while maintaining passband flatness, the viscous damping B [N/(m/s)] is generally set – often with the aid of an external damping resistor not modeled here – so that the dimensionless damping constant ζ_0 is approximately $1/\sqrt{2}$.

Passive seismometers have the obvious advantage of requiring no power to operate. Indeed the device is literally a generator, albeit one which produces very little power. However, modern digital seismology requires that some power be expended on digitization and subsequent

telemetry or storage, so the seismograph system as a whole always consumes some power.

The chief disadvantages of passive seismometers for recording ground motion at long periods are:

- (a) The suspension system and velocity transducer have nonlinearities as a function of the displacement of the proof mass from equilibrium. These nonlinearities can cause excursions in the output signals which cannot be removed by post-processing.
- (b) Large masses and compliant suspensions are required to achieve high sensitivity at long periods, making for an instrument, which is physically large, difficult to construct and susceptible to damage when being transported.
- (c) Conflicting damping requirements: As we shall see below, the damping must be as low as possible in order to minimize self-noise, but for a flat transfer function the damping must be set to a level much higher than the minimum. A transfer function which is strongly peaked will have a corresponding “notch” in its clip level, limiting its ability to record during large or nearby events.

A force-feedback or “active” seismometer solves these problems by taking a mechanical system like that of the passive seismometer, as shown in Fig. 3, and adding a displacement transducer T , as shown in Fig. 5. In an active seismometer, the voice coil G is used to produce a force on the proof mass by driving it with a feedback current i_f instead of using it to produce a voltage proportional to the velocity of the proof mass.

It is a remarkable fact that every generator is also a motor. The force transducer in the feedback path of an active seismometer has the same physical configuration as the velocity transducer at the output of a passive seismometer. Moreover the electromotive force generated per unit of velocity or “motor constant” of the former in V/(m/s) is identical to the force generated per unit of current or “generator constant” of the latter in N/A:

$$G = \frac{e}{\dot{x}} = \frac{f}{i} \left[\frac{\text{V}\cdot\text{s}}{\text{m}} = \frac{\text{N}}{\text{A}} \right]$$

The displacement transducer shown in Fig. 5 is generally one of two types. A linear-variable differential transformer (LVDT) is effectively a transformer where the coupling to the secondary winding(s) is a function of the position of a movable magnetic core. A capacitive displacement transducer (CDT) is a capacitor where the

capacitance is varied by changing the spacing or overlapping area of the capacitor plates. In order to reduce nonlinearity and increase sensitivity, transducers of both types are normally implemented as part of a bridge circuit, requiring three windings in the case of an LVDT or three capacitor plates in the case of a CDT. In both cases the displacement transducers operate at a carrier frequency well above the passband of the instrument, and the outputs require demodulation back down to the passband before they are passed on to the compensator, output, and feedback stages.

The feedback loop is closed using feedback electronics which take the displacement transducer output voltage and produce an appropriate feedback current as shown in the block diagram of Fig. 6. Two main blocks of interest in the feedback electronics are a compensator $C(s)$ in the forward path and the feedback network itself.

Discussions of the components, design, or limitations of the compensator are beyond the scope of this entry, but suffice it to say that the challenge is to simultaneously ensure high loop gain and stability and that the compensator design determines the shape of the roll-off of the closed-loop transfer function at high frequency.

A few of the key components in the feedback network are explicitly indicated in Fig. 6, namely, the “differential” feedback capacitor C_D , a “proportional” feedback resistor R_P , and an “integral” feedback resistor R_I . The integrator time constant

Principles of Broadband Seismometry, Fig. 5 Mechanical schematic of an active inertial sensor

Principles of Broadband Seismometry, Fig. 6 Block diagram of an active inertial sensor using force feedback

τ_I is another key parameter of the feedback circuit.

Feedback control systems have the property that as long as the loop gain is sufficiently high (and the system is stable), the transfer function of the system is the inverse of the feedback transfer function (Phillips and Harbor 1991). In the case of an inertial sensor, this means that the transfer function is determined by electronic components in the feedback network not the physical characteristics of the pendulum. Furthermore this same feedback holds the proof mass substantially at rest with respect to the frame of the sensor, greatly reducing the impact of nonlinearities in the suspension and transducers.

Thus, for high loop gain, a good approximation of the transfer function of the active seismometer of Fig. 6 is

$$\frac{V_o}{sX_i} = \frac{M}{GC_D} \frac{s^2}{s^2 + \frac{1}{C_D R_P} s + \frac{1}{C_D \tau_I R_I}} \left[\frac{\text{V}\cdot\text{s}}{\text{m}} \right]$$

By comparison with the standard form of a second-order transfer function (1), we can write expressions for the sensitivity, corner frequency, and damping of this force-feedback seismometer:

$$S = \frac{M}{GC_D}$$

$$f_o = \frac{\omega_0}{2\pi} = \frac{1}{2\pi} \sqrt{\frac{1}{C_D \tau_I R_I}}$$

$$\zeta_0 = \frac{1}{2C_D R_P \omega_0} = \frac{1}{2R_P} \sqrt{\frac{\tau_I R_I}{C_D}}$$

The properties which make an active force-feedback seismometer a good tool for broadband weak-motion seismology become apparent:

- (a) The effects of nonlinearities as a function of displacement of the proof mass from its rest position are greatly reduced, using a displacement transducer and high loop gain.
- (b) High sensitivity at long periods is achieved by selecting components in the feedback path. In order to achieve a particular natural

frequency, the electronic components required in a force-feedback seismometer are much smaller than the mechanical components required in a passive seismometer with the same response.

- (c) The damping of the pendulum can be made low without affecting the closed-loop response of the system, since the damping ζ_0 of the closed-loop system is determined entirely by the components in the feedback network.

The power required to operate a force-feedback seismometer must be considered its chief disadvantage relative to a passive seismometer. Although the power consumption can often be kept to a fraction of the rest of the recording system, the fact that power must be provided at all does increase the size and complexity of cables, connectors, and the digitizer itself. The versatility of the broadband seismometer relative to passive alternatives, however, can more than make up for this.

Ground Motion Spectra

The sensing of ground motion due to earthquakes and other phenomena is fundamentally limited by the background motion of the earth. Efforts to define minimum, maximum, and typical ground motion models go back at least as far as the 1950s (Brune and Oliver 1959).

An important current standard consists of the new high- and low-noise models (NHNM and NHNM) (Peterson 1993) which in practice sets limits on the typical background motion at well-constructed vaults. It represented an improvement over the old noise models (OLNM and ONHM) because it included stations with the then-new STS-1 seismometer, the first high-quality very broadband sensor. These four models are plotted in Fig. 7 below.

In the band 0.05–1 Hz all models of ground motion are dominated by a peak called the microseismic peak. This peak is in fact made up of two peaks. The first peak, typically between 10 and 16 s period, corresponds to the natural period of waves generated by storm winds in mid-ocean. This peak is sometimes called the primary

Principles of Broadband Seismometry,

Fig. 7 Models of ground motion spectra

microseism. Because the mean pressure at the ocean bottom is proportional to the square of wave height, standing waves at mid-ocean produce a larger, double-frequency peak between 4 and 8 s period (Longuet-Higgins 1950). Ocean microseisms dominate recordings made by sensors with sufficiently low self-noise and divide ground motion into two important bands, commonly called short period (above the microseismic peak) and long period (below the microseismic peak).

Peterson dealt with the non-stationarity of the nonetheless random processes underlying the background motion of the earth by simply discarding time segments containing earthquakes or noise bursts. More recent models of ground motion spectra deal with the problem of non-stationarity in a more sophisticated way, using statistical approaches which evaluate the probability distribution of the power spectral density (PSD) as a function of frequency.

For example, studies of the Global Seismological Network (GSN) resulted in noise models of vertical (Z) and horizontal (H) ground motion (GSNNMZ and GSNNMH, respectively) (Berger et al. 2004), and a study of the continental United States has produced the mode low-noise

model (MLNM) (McNamara and Buland 2004): both studies employ the notion of the PSD probability density function (PDF) to produce estimates of ground motion spectra at quiet sites. Figure 8, reprinted from Figure 8 of McNamara and Buland (2004), shows how transient phenomena (e.g., calibration signal injected into the seismometer) are represented alongside stationary phenomena (e.g., the microseismic peak) using this approach.

The PSD PDF allows a more precise statistical definition of ground motion low-noise models. For example, the MLNM was constructed as the per-frequency minimum of the *modes* of the PDF of a set of broadband seismic stations distributed across the continental United States. Similarly, the GSNNM is the per-frequency minimum of the 1st (quietest) percentile of the PDF of the stations in the GSN. As shown in Fig. 7, the GSNNMZ is lower than the NLNM at very long periods (<0.01 Hz); this new lower limit is likely to still be limited by the performance of the STS-1.

Despite the advance in network performance monitoring that the PSD PDF represents, the NLNM remains the standard by which seismometer self-noise floors are measured, and many of

Principles of Broadband Seismometry,

Fig. 8 Typical acceleration power spectral density probability density function

the most common features of background ground motion are represented relative to the NLNM and NHNM.

Some strong generalizations can be made about background motion at long periods:

- Horizontal components are never quieter than vertical components at a given location. See section on “[Tilt](#).”
- Sites on alluvium are never quieter than nearby sites on hard rock. See section on “[Site Selection](#).”
- Surface sites are never quieter than nearby underground sites. See section “[Downhole and Ocean-Bottom](#).”

Indeed, the NHNM at long periods is made up of horizontal ground motion records at surface vaults on alluvium, while the NLNM at long periods is made up of vertical records on hard rock, mainly in subsurface vaults (Peterson 1993).

There are fewer features of ground motion at short periods (above the microseismic peak) which can be generalized. As at long periods, surface sites are never quieter at short periods than nearby underground sites, but horizontals and verticals tend to have similar levels. In both

bands “cultural noise” such as that due to traffic can be problematic, as can noise due to wind in trees or running water. Finally, there is always a minimum in the ground noise spectrum at or just above 1 Hz.

Although the NLNM was constructed from the records of land-based seismometers, it may also represent a hypothetical quietest site under the sea. Seismic noise surveys on the ocean bottom have not yet been undertaken on the scale that they have been on land. It is clear from the work which has been done so far, however, that the noise levels are generally significantly higher. Most of the ocean floor is covered with sediment which is more compliant than sediment on land, and seismic velocities are lower. Seafloor compliance means that excess site noise due to deformation and tilt can result from both variations in pressure due to waves at the surface and currents traveling along the bottom of the ocean (Webb and Crawford 2010). When precautions are taken to mitigate these effects, site noise can approach the levels observed on land.

In conclusion, although models based on larger or more regionally focused samples of sites exist, and although statistical methods have improved with time, Peterson’s NLNM remains the standard by which the noise performance of

broadband seismometers and sites are judged. It represents a hypothetical “quietest site on earth” so a good broadband seismometer should be able to resolve it. The NLNM is therefore commonly used as a reference curve on plots of broadband seismometer self-noise. In turn, at the very longest periods, it may be that the NLNM is limited by the available broadband sensor technology.

Ground Motion Unit Conversion

Ground motion can be expressed in the time domain units of displacement [m], velocity [m/s], or acceleration [m/s²]. In the frequency domain, a ground motion signal can furthermore be represented either as an amplitude spectrum [“per Hz,” e.g., m/s²/Hz] or as a PSD [“per $\sqrt{\text{Hz}}$,” e.g., m/s²/ $\sqrt{\text{Hz}}$]. In assessing the performance of a seismograph station, it is essential to be able to convert between various units fluently.

For example, comparison of earthquake spectra (typically a displacement amplitude spectrum or peak band-passed acceleration spectrum) to the clip level of a station (typically a maximum amplitude of acceleration or velocity) allows determination of the maximum earthquake magnitude which can be detected without clipping. Similarly, comparison of the same event spectra to seismograph self-noise or site noise (typically represented as an acceleration PSD) determines the minimum detectable magnitude. Finally, comparison of seismometer clip and self-noise levels as a function of frequency gives the clearest representation of seismometer dynamic range.

Acceleration-Velocity-Displacement

The simplest kind of conversion is integration and differentiation to obtain different time derivatives of ground motion. For example, to convert an acceleration to a velocity or from velocity to displacement at a given frequency f , one simply divides by the amplitude by the angular frequency $\omega = 2\pi f$. This follows straightforwardly from the equivalence of differentiation in the time domain to multiplication in the frequency domain by the Laplace frequency $s = j\omega$. Thus for sinusoidal amplitudes of acceleration $|a|$,

velocity $|v|$, and displacement $|d|$ at frequency f , the following relations hold:

$$|a| = 2\pi f |v| \quad (2)$$

$$|v| = 2\pi f |d| \quad (3)$$

These relations have wide applicability in converting amplitude spectra of finite energy signals of earthquakes between acceleration, velocity, and displacement and in converting PSDs of stationary between acceleration, velocity, and displacement.

Another type of conversion is needed for the comparison of finite energy signals and stationary signals. In particular, conversion from a PSD to the equivalent amplitude requires that a minimum of two factors be specified: a bandwidth and a crest factor.

Relative Bandwidth

Parseval’s theorem can be used to compute the root-mean-square amplitude a_{RMS} expected given the one-sided power spectral density as a function of frequency $a_{\text{PSD}}(f)$ and lower and upper frequency band limits $f_H > f_L$:

$$a_{\text{RMS}}^2 = \int_{f_L}^{f_H} a_{\text{PSD}}^2(f) df$$

This equation applies equally well to acceleration, velocity, or displacement, but note that if the RMS is in units, then the PSD is in units/ $\sqrt{\text{Hz}}$.

For narrowbands the spectrum can be assumed to be constant within the band so that

$$a_{\text{RMS}}^2 = a_{\text{PSD}}^2(f_H - f_L) = a_{\text{PSD}}^2 k_{\text{RBW}} f \quad (4)$$

$$a_{\text{RMS}} = a_{\text{PSD}} \sqrt{k_{\text{RBW}} f}$$

where the “relative bandwidth factor” is defined as

$$k_{\text{RBW}} \equiv \frac{f_H}{f} - \frac{f_L}{f}$$

Principles of Broadband Seismometry,
Table 1 Common choices of relative bandwidth

Bandwidth	b	n	k_{RBW}	$k_{\text{RBW}} _{\text{dB}}$
Octave	2	1	0.707	-1.5
1/6 decade	10	6	0.386	-4.1
1/2 octave	2	2	0.348	-4.6
1/3 octave	2	3	0.232	-6.4

It is common to define bands as a fraction $1/n$ of either an octave ($b, 2$) or a decade ($b, 10$), as follows:

$$\frac{f_H}{f_L} = b^{\frac{1}{n}}$$

and furthermore to dispose the band limits symmetrically (in a logarithmic scale) around the band center, so that

$$\frac{f_H}{f} = \frac{f}{f_L} = b^{\frac{1}{2n}}$$

so that the relative bandwidth factor k_{RBW} for various bandwidths can be evaluated using

$$k_{\text{RBW}} = b^{\frac{1}{2n}} - b^{-\frac{1}{2n}}$$

Some common choices of bandwidth are listed in Table 1. Two which appear commonly in seismometer specifications, 1/2 octave and 1/6 decade, are close enough that they are often considered interchangeable. The octave bandwidth is considered typical of a passive seismometer and has been used in some important studies of typical earthquake spectra (Clinton and Heaton 2002).

The choice of a relative bandwidth thus permits conversion of a power spectral density to an equivalent RMS amplitude.

Crest Factor

The second factor needed when comparing stationary and transient signals is called a “crest factor,” and is defined as the ratio of peak amplitude to RMS amplitude. The correct choice of crest factor depends on the nature of the signal in question. Broadband Gaussian noise will

surpass its standard deviation 32 % of the time and twice the standard deviation 5 % of the time, for example. These conditions would correspond to crest factors of 1 and 2, respectively.

The signals which make up background ground motion do often have Gaussian distributions (Peterson 1993), as do the self-noise of seismometers and digitizers. When a Gaussian signal is passed through a narrowband filter, the peak amplitudes of the signal which results have a Rayleigh distribution (Bormann 2002), corresponding to a crest factor:

$$k_{\text{crest}} = \sqrt{\frac{\pi}{2}} \cong 1.25$$

Given a crest factor, the equivalent amplitude can be estimated from a PSD using

$$a_{\text{peak}} = a_{\text{RMS}} k_{\text{crest}} \quad (5)$$

As with the equations accounting for relative bandwidth, this equation applies equally well to acceleration, velocity, or displacement.

Decibels

Ground motions are often expressed in decibels. By convention the reference amplitude for the decibel in this context is the corresponding metric unit. For example, an acceleration PSD is converted to dB using

$$a_{\text{PSD}}|_{\text{dB}} = 20 \log_{10} \left(\frac{a_{\text{PSD}}}{\frac{\text{m}}{\text{s}^2 \sqrt{\text{Hz}}}} \right)$$

while a velocity amplitude is converted using

$$v_{\text{peak}}|_{\text{dB}} = 20 \log_{10} \left(\frac{v_{\text{peak}}}{\frac{\text{m}}{\text{s}}} \right)$$

Thus, the various unit conversions of Eqs. 2, 3, 4, and 5 become:

$$a|_{\text{dB}} = v|_{\text{dB}} + 20 \log_{10} \left(\frac{2\pi f}{\text{rad}} \right) \quad (6)$$

Principles of Broadband Seismometry,

Fig. 9 Representative station (noise) and small event (signal) spectra

Principles of Broadband Seismometry, Fig. 10 Components of a seismograph station

$$v|_{\text{dB}} = d|_{\text{dB}} + 20\log_{10}\left(\frac{2\pi f}{\text{rad}}\right) \quad (7)$$

$$a_{\text{RMS}}|_{\text{dB}} = a_{\text{PSD}}|_{\text{dB}} + 10\log_{10}(k_{\text{RBW}}) + 10\log_{10}\left(\frac{f}{\text{Hz}}\right) \quad (8)$$

$$a_{\text{peak}} = a_{\text{RMS}}|_{\text{dB}} + 20\log_{10}(k_{\text{crest}}) \quad (9)$$

These relations can be seen in action Fig. 13 below, where the band-passed peak velocity amplitudes of earthquakes are compared to the clip level and noise floor of a seismometer.

Components of Station Noise

The noise power at a seismic station is the sum of the noise powers of the seismograph and the background motion at the site:

$$\langle |\ddot{x}_{\text{station}}|^2 \rangle = \langle |\ddot{x}_{\text{seismograph}}|^2 \rangle + \langle |\ddot{x}_{\text{site}}|^2 \rangle$$

It is important that the station noise be low enough to not obscure the signals of interest when they arrive. This is shown in cartoon form in Fig. 9.

A modern seismograph station consists, in turn, of a seismometer and a digitizer, as shown schematically in Fig. 10. Both elements must be considered in determining the performance of the station as a whole.

Similarly the clip level of a seismograph station is a combination of the clip level of the seismometer and of the digitizer. A difference is that whereas noise powers are summed, the clip level of a system is the minimum of the clip level of all of the components, when referred to common units.

The importance of the sensitivity of a digitizer is now apparent. The sensitivity must be high enough to minimize the digitizer's contribution to the station noise, but at the same time it must be low enough that the clip level of the digitizer does not degrade the station clip level so much that events of interest will be clipped. Note that a system incorporating a seismometer which achieves a high sensitivity to ground motion using a high-gain output stage is equivalent to a system in which the digitizer subsystem includes a preamp with the same gain.

The self-noise of seismometers can be divided roughly into those that are stationary, in the sense that the probability distribution does not change with time, and those that are nonstationary.

Of the sources of stationary noise in a seismometer, there are two main subcategories, called "white" noise and "flicker" noise sources. White noise sources have the same amount of noise power per unit of (absolute) bandwidth in frequency; flicker noise sources have the same amount of noise power per fractional (relative) bandwidth, for example, per octave or per decade. The PSD of a white noise source is independent of frequency; the PSD of a flicker noise source varies as the inverse of frequency (Motchenbacher and Connelly 1993), i.e., proportional to $f^{-\alpha}$ where typically α is close to 1 but can be as high as 1.5.

In the process of referring the noise at various points in the feedback loop to the input of a seismometer, each source must be referred to the sensor input. This is similar to converting ground motion units from velocity to displacement and from displacement to velocity. Thus in principle various components of the noise floor of a seismometer can be proportional to f^n (or equivalently a slope of $10n$ dB/decade) where n is any positive or negative number, usually an integer. In practice, in a well-designed force-feedback seismometer, the equivalent acceleration PSD of the self-noise will be proportional to f^{-3} (−30 dB/decade) at low frequencies and proportional to f^4 (40 dB/decade) at high frequencies (Hutt and Ringler 2011).

For example, the displacement transducer in a feedback seismometer results in a white noise

proportional to displacement, but to determine the equivalent acceleration, a double integration is required, so the slope of the acceleration PSD is f^4 , and this tends to dominate the self-noise of the sensor at high frequencies. Similarly the digitizer white noise component, when converted from velocity to acceleration PSD, has a f^2 (20 dB/decade) characteristic and will tend to dominate the station noise near 10 Hz.

Two noise sources common to all seismometers, active and passive, are Johnson and Brownian noise. Johnson noise is a noise source due to thermal agitation of the electrons that make up the current flow in a resistor. For a resistance R [Ω] at temperature T [K], the expectation value of the voltage PSD across its terminals will be:

$$\langle |e_n|^2 \rangle = 4k_b TR$$

where $k_b = 1.38 \times 10^{-23}$ J/K is Boltzmann's constant. For low noise, resistors must have small values, but this generally results in greater power consumption.

Brownian noise is similar to resistor noise, both in terms of the statistical mechanics which explain it, and in the white noise spectrum which results. In particular, the Brownian motion of the boom of a pendulum results in an equivalent acceleration PSD of the frame of that pendulum equal to:

$$\langle |\ddot{x}_n|^2 \rangle = \frac{4k_b TB}{M^2}$$

Thus it is clear that for low noise, the proof mass must be large while the viscous damping must be small. All known voice-coil and capacitive transducers require narrow gaps for high sensitivity; this is a source of viscous damping and can only be avoided by pumping the pendulum enclosure down to a hard vacuum, something quite difficult in practice. The downside of large proof masses is increased size and fragility; many broadband seismometers required masses to be locked during transportation.

Nonstationary noise sources are also very important to the overall performance of a seismometer. A common example of nonstationary noise is what is sometimes referred to colloquially as a “pop.” The characteristic waveform is a randomly occurring disturbance having the shape of the impulse response of the seismometer. When such a signal is referred to the input of the seismometer, it turns out to correspond to a sudden step change in acceleration at the input to the seismometer, equivalent to a sudden step change in tilt of the instrument. Because “pops” occur at random times, they contribute a f^{-2} characteristic to the acceleration PSD noise spectrum.

“Pops” are often associated with temperature transients associated with initial installation and power-on. However, some sensors, which are poorly designed or have been insufficiently tested or damaged during handling, will exhibit an unusual susceptibility to pops after initial installation, and the excess “pop” noise will subsequently never die down to an immeasurable level. “Pop” noise is a low-frequency phenomenon which happens intermittently on a very long time scale. This is why, during testing of broadband seismometers, it is imperative to test sensors for a relatively long period of time, on the order of days or weeks, and include all data collected on a statistical basis, giving the median and maximum noise levels as much attention as the minimum noise level.

The PSD PDF (see section “[Ground Motion Spectra](#)”) is a particularly useful tool in performing this type of analysis. Figure 8 shows how the PSD PDF represents rare, transient events such as mass-centering operations are captured in the maximum of this distribution, while the typical behavior is captured in the mode. This allows the whole available record to be analyzed, without “window-shopping.” This is as it should be: single-occurrence “pops” can be as much of a problem in interpreting seismograms as stationary noise sources and should therefore be considered just as much a part of the overall self-noise performance. See ► [Seismometer Self-Noise and Measuring Methods](#).

Selection Criteria

Many factors need to be taken into consideration in choosing a broadband seismometer. Self-noise, clip level, and transfer function are the basic performance criteria, while power and size can crucially determine the cost of the overall installation. These factors and others are treated in this section.

Sensor Self-Noise

Broadband seismometers are required to have a self-noise less than the NLNM, a hypothetical “quietest site on Earth,” at least over some wide band. The self-noise cannot be measured deploying the sensor where there is no ground motion: the NLNM shows that there is no such place on Earth. Modern methods require at least three sensors be installed side by side on a rigid pier and a coherence-based analysis technique (Sleeman et al. 2006; Evans et al. 2010). Careful management of thermal, magnetic, and pressure shielding is required (see section on “[Installation Procedures](#)”), particularly to observe the performance of the best sensors at very long periods.

One comprehensive self-noise study (Ringler and Hutt 2010) includes all the important broadband seismometers as of its writing. Figures 11 and 12, reprinted from Figures 13 and 14 of that study, show the lowest 5th percentile and median noise of each sensor, respectively.

The abbreviations used in Figs. 11 and 12 are the same as those used in Table 2 below with the following exceptions: T-120, T-240, and T-Compact are the Nanometrics Trillium 120, Trillium 240, and Trillium Compact, respectively, and the 151–120 was the predecessor of the Geotech 151B-120. It is also worth noting that the STS-2 performance shown in these figures is that of a model with higher gain at 20,000 V·s/m and a correspondingly lower clip level, and that the CMG-3TB tested was a borehole variant of the standard CMG-3T.

The median self-noise was for some sensors close to the 5th percentile, while for others it was significantly higher. This can be taken as an indicator of the uniformity and/or the temporal stability of the sensors. The peak in the noise floors

Volumes are for three components and are derived from footprint area and height alone

directly under the microseismic peak is not a feature of the sensor noise floor, but an artifact of imperfect misalignment correction.

Given the importance of the NLNM in setting the target performance of broadband seismometers, it is understandable that self-noise requirements are often specified in terms such as “below the NLNM from 30 s to 30 Hz.” Although the intention is clear, this is unfortunately a poor choice of wording. In some bands the NLNM is very steep – which is to say that the typical background acceleration PSD at a quiet site is also very steep – and so a great reduction in self-noise may not result in much improvement in the frequencies at which the self-noise crosses the NLNM. Conversely, where the slope of the NLNM is quite similar to that of the self-noise of a seismometer, a small improvement in self-noise will produce an exaggerated improvement in the NLNM-crossing frequency. Finally, care must be taken at high frequencies because the NLNM is simply not defined above 10 Hz (similarly the MLNM does not extend above 10 Hz and the GSNM does not extend above 13 Hz).

A better way to set a specification on seismometer self-noise is to pick two key frequencies near the edges of the band of interest and set limits in dB at those frequencies. For example,

to require the “median self-noise below –185 dB at 0.01 Hz and below –168 dB at 10 Hz” is equivalent to being “below the NLNM from 100 s to 10 Hz,” but for the purposes of comparing one seismometer to another, it is more instructive to compare their median performance in dB at specified frequencies than in the NLNM-crossing frequencies in Hz.

Clip Level

The largest measured ground motions resulting from earthquakes have approached peak accelerations of 40 m/s² and peak velocities of 3 m/s, although these limits tend to increase with the densification of networks and the passage of time (Strasser and Bommer 2009). No seismograph can measure both the largest and the smallest ground motions. The dynamic range of the current state of the art in analog-to-digital converters is insufficient to cover the >170 dB range required. Although weak-motion seismometers focus on measuring the smallest motions, they are still expected to measure relatively large motions without clipping, so that weak-motion studies are not “interrupted” by strong motion.

Whether the clip level of a particular seismometer is adequate depends on the expected levels of ground motion at the site of deployment.

Principles of Broadband Seismometry,

Fig. 13 Earthquake ground motions and seismograph clip levels and noise floors

The ground motion resulting from an earthquake varies with the magnitude but also with the distance from the event.

The ground motion resulting from earthquakes is a function of frequency. Figure 13 shows the typical ground motions for large and small earthquakes at local (10 km), regional (100 km) and teleseismic (3,000 km) distances (Clinton and Heaton 2002).

These event spectra are plotted for comparison against the noise floor and clip level of a representative broadband seismograph. It can be seen that the digitizer noise floor is limiting the

performance of the seismograph system for frequencies above the microseismic peak. The station operator could choose to increase the digitizer preamp gain or equivalently install a high-gain version of the seismometer. This would result in a reduction of the contribution of the digitizer to the system noise and therefore make it possible to see smaller events, but it would also reduce the clip level of the system, so that large events would be more likely to clip.

The clip level of a seismometer in the middle of its passband depends solely on the output clip level in volts and its sensitivity. Notwithstanding

a hypothetical seismometer which runs from very high voltage rails, a requirement for high clip level is low sensitivity, and vice versa. The sensitivity and clip levels of some representative broadband seismometers are given in Table 2, along with other critical performance criteria.

Broadband seismometers generally use displacement transducers to measure the relative displacement of the proof mass and the frame. The proof mass and its suspension together make a pendulum which has a response which is flat to acceleration and independent of its natural frequency above the natural frequency.

There is usually a critical frequency above which the clip level of a broadband seismometer becomes more or less flat to acceleration. For the seismometer depicted in Fig. 6, the acceleration clip level is 0.17 g and the velocity clip level is 16 mm/s, so this critical frequency is near 16 Hz. If this critical frequency is significantly higher than the peak frequency of the spectra of events of interest, it will not affect clipping behavior for real seismic signals.

Response

It is crucial to understand the transfer function of a broadband seismometer when converting a recording in counts or volts back to appropriate units of ground motion. It is a common mistake to think that the signals at frequencies below the lower -3 dB corner or above the upper -3 dB corner are not useful. In fact the only thing which determines whether or not useful signal is present is signal-to-noise ratio, as illustrated by Figs. 9 and 13. With careful application of the inverse response, useful estimates of ground motion can be obtained well outside the -3 dB band.

Seismometers are sometimes available with different options for lower or upper corner frequency and for the mid-band sensitivity. Note that the term “sensitivity” in the context of seismometers is interchangeable with “generator constant” and will have units of voltage per unit of velocity. When selecting a seismometer, it is important to have in mind the largest signal which is likely to be observed, given the seismicity of the nearest seismogenic zone. Seismic risk

maps are invaluable for determining the probability of recurrence of a given peak ground acceleration or velocity, which can then be directly compared to the configured seismograph system clip level. High sensitivity means the contribution of the digitizer to the station noise floor is reduced, but it also means the system clip level is reduced. Some users will prefer to use a low-gain seismometer and a digitizer with a built-in variable-gain preamp, so that they can “dial in” the correct station sensitivity after installation.

One feature of a seismometer not normally represented in its nominal transfer functions is the phenomenon of parasitic resonances. Well-characterized seismometers will have a specification for the lowest mechanical resonance; it is important to make sure that this frequency is above the range of frequencies of interest in a particular study.

Power

There are two advantages to low power. The first is that lower power means a physically smaller footprint and a less costly installation for stations which must be located far from main power systems. Such stations are common because the best seismic sites are generally located away from roads and cities and human activity in general, so-called sources of cultural noise. For a temporary deployment, lower power means fewer batteries are needed for a given length of time. For a permanent deployment at a remote site, lower power means less on-site power generation (e.g., fewer solar panels) is needed. A smaller footprint for power generation furthermore generally means less wind-induced seismic noise.

A second advantage to lower power relates specifically to performance at very long periods in vault-type installations. Power dissipation inside the sensor and digitizer means heat generation. This heat causes convection within the vault, and the resulting airflow tends to be turbulent and chaotic, heating and cooling various surfaces around the vault, in particular the floor, causing small but measurable tilts. Thus, for sensors which consume more power, it becomes more difficult to properly thermally shield well

enough to drive the resulting apparent horizontal accelerations down below the NLNM at very long periods.

The power consumption of some broadband seismometers is listed in Table 2.

Size and Weight

The physical size of a seismometer has a multiplying effect on the size and thus the cost of deployment of a seismic station. For vault installations, a larger sensor requires a larger volume to be reserved for thermal shielding. Since a good broadband vault must generally be built below ground level, a larger sensor means the minimum volume which must be dug out for the vault is larger.

For temporary deployments, the size and weight of a sensor can significantly affect ease of deployment. When it is a matter of driving to a remote location and hand-carrying the equipment even further away from the road, it can mean that significantly fewer stations can be set up per day, if the sensor is large and heavy.

Aside from the trouble it causes in a temporary deployment, a heavy sensor has an advantage over a light one, in that the associated thermal mass means better temperature stability.

The volume and weight of some broadband seismometers are listed in Table 2.

Enclosure, Leveling, and Topology

The choice of enclosure for broadband seismometers is an important one. Some common options are vault, borehole, posthole, and ocean bottom.

Enclosures designed for deployment in vaults need to be dust- and watertight, but are generally not designed for submersion to significant depths or durations (i.e., ingress protection ratings of IP66 or IP67 are common, but not IP68). There is no particular restriction on the overall diameter of a vault enclosure, but it should be designed for ease of leveling, orientation, and thermal isolation. For example, the connector should be oriented to allow cables to exit the enclosure horizontally near the surface of the pier. This makes it easy to strain-relieve the cable, minimizing the possibility of cable-induced noise, and

to place an insulating cover over top of it. The design of broadband seismometer vaults is described in “[Installation Procedures](#)” below.

Enclosures designed for deployment in cased boreholes generally need to have smaller diameters and a mechanism to lock the sensor in the hole. Drilling of boreholes is always more economical for smaller diameters than larger ones; a common casing diameter for broadband seismometers is 15 cm. The connector will generally exit at the top of the sensor and the whole assembly should be rated for continuous submersion to a significant depth (i.e., IP 68 to 100 m or more), since flooding of boreholes is common. Boreholes stray from verticality as they are dug deeper; a remote leveling range of up to $\pm 4^\circ$ is thus typically required. See ► [Downhole Seismometers](#) for a more detailed discussion.

Enclosures designed for deployment in shallow uncased holes called postholes do not need hole locks. Sensors are generally emplaced in backfilled soil or sand and are simply pulled out or dug out at the end of the deployment. As with borehole sensors, the connector should generally exit at the top and must be rated for submersion. There is less control of sensor leveling with deeper holes, and a remote leveling range of $\pm 10^\circ$ may be required. See ► [Downhole Seismometers](#) for a more detailed discussion.

Enclosures designed for ocean-bottom deployment have several requirements which other sensor types do not. Most of the ocean bottom is near 5 km depth, so in order to be deployable over most of the ocean bottom, a sensor would typically have a continuous submersion rating of 6 km. Most ocean-bottom deployments are done by releasing the sensor at the surface and without controlling exactly where it will come to rest on the ocean floor. The sensors are designed to level themselves, typically at a predetermined time after release, and since the exact resting place is not known in advance, a self-leveling range of $\pm 45^\circ$ or more is required. Prevention of corrosion and biofouling is additional crucial requirement for ocean-bottom enclosures. See ► [Ocean-Bottom Seismometer](#) for more information.

When an underground vault in bedrock is available, for example, in an inactive mine or in the basement of a building, then a vault-type enclosure is of course the best choice. When there is some significant overburden, so that to reach bedrock a borehole must be dug and cased, then a borehole-type enclosure is required. And of course ocean-bottom deployments require an ocean-bottom enclosure.

It is not uncommon however that a sensor must be deployed in a location where no preexisting vault or borehole is available. In such situations a posthole installation can give performance as good or better than a vault built according to best practices, at significantly less cost for the overall installation.

If leveling motors are included in the sensor, a remote leveling process is initiated via an external electrical signal or at a configurable time after power-on; otherwise manual leveling by adjustment of set screws is sometimes needed. All enclosure types except vault enclosures require remote leveling capability.

Sensor axis topology is a final consideration. Some studies may require only a single axis of seismic sensing, usually vertical. For triaxial seismic sensing, the sensor outputs should be horizontal (X, Y) and vertical (Z). However certain kinds of installation troubleshooting are easier to do if the internal sensing axes are not aligned to horizontal and vertical. See ► [Symmetric Triaxial Seismometers](#) for more information.

Environmental Sensitivities

Spurious signals due to environmental sensitivities are not normally considered part of the self-noise of a seismometer, but they can deleteriously affect the output signal in many of the same ways. Broadband seismometers are particularly sensitive to changing tilt, temperature, pressure, and magnetic fields.

To understand why, consider that in order to have self-noise just equal to the NLNM at 100 s period, you need to be able to discriminate ground motion from all other effects at a level of

$$a_{\text{PSD}} = 10^{\frac{-185}{20}} \frac{\text{m}}{\text{s}^2 \sqrt{\text{Hz}}} = 0.56 \frac{\text{nm}}{\text{s}^2 \sqrt{\text{Hz}}}$$

And since the self-noise of a seismometer is typically proportional to $1/f$ in this band, the noise in the decade around $f_{\text{PSD}} = 0.01$ Hz will be

$$a_{\text{NLNM}} = a_{\text{PSD}} \sqrt{f_{\text{PSD}} \ln(10)} \frac{\text{nm}}{\text{s}^2} = 0.08 \frac{\text{nm}}{\text{s}^2}$$

This tiny acceleration, measurable by very broadband seismometers (i.e., a weak-motion inertial sensor with a wide dynamic range over a very broadband), can be overwhelmed by spurious environmental sensitivities, as discussed below.

Tilt

Sensitivity to tilt is an inevitable consequence of inertial sensing, because gravitational equivalence principle tells us that gravity is indistinguishable from accelerations. An inertial sensor tilted from vertical by an angle θ measured in radians experiences an apparent horizontal acceleration of

$$\ddot{x} = g_0 \sin \theta$$

where $g_0 \cong 9.8 \text{ m/s}^2$ is the standard acceleration due to gravity near the surface of the Earth. For small tilt angles $\sin \theta \cong \theta$, so all inertial seismometers have the same tilt sensitivity α_T , that is, the same apparent horizontal acceleration in response to tilt:

$$\alpha_T \equiv \frac{\ddot{x}}{\theta} = g_0 \cong 9.8 \frac{\text{m/s}^2}{\text{rad}} \cong 0.17 \frac{\text{m/s}^2}{^\circ}$$

Some tilt and rotation is to be expected to accompany the translational motion of a traveling seismic wave, but locally generated non-seismic tilt can prevent critical observations from being made. It is because of their extreme sensitivity to tilt that all inertial translational sensors, including broadband seismometers, record higher levels of apparent horizontal motion than vertical motion at long periods.

In order to resolve the NLNM at 100 s, tilts in the decade band around that frequency would have to be kept smaller than

$$\Delta\theta = \frac{a_{\text{NLNM}}}{g_0} = 5 \times 10^{-10} \text{ }^\circ$$

This is an extremely small angle. It corresponds to lifting one side of a 10 m wide structure pier by just 1 Å, the order of magnitude of atomic radii.

Fortunately, locally generated “excess” tilt is not spontaneous but driven by some other environmental factor and can be greatly reduced with careful vault design. For example, it is common for such tilts to be driven by temperature or pressure sensitivity of the seismic vault or nearby subsurface geology. Tilts can also be driven by changes in insulation or water table, vehicular traffic or other cultural activity, or wind loading on nearby structures. Mitigating these sorts of effects is an overriding concern in designing a seismic vault, as described in the section “[Installation Procedures](#).”

Another, more subtle tilt-related effect is that a static tilt will increase off-axis coupling of horizontal motion into vertical. See ► [Symmetric Triaxial Seismometers](#) for more information. Other than this effect, the actual static tilt of a seismometer is generally not a problem, as long as it is within the operating range of the seismometer.

Most broadband seismometers have an integrator in the feedback circuit, and the operating range of this part of the circuit determines the tilt range of the seismometer. For the lowest possible noise at very long periods, the integrator output resistor must be large, and this restricts the tilt range of the seismometer. Thus very broadband seismometers are typically equipped with centering motors or leveling platforms to extend this tilt range. See ► [Downhole Seismometers](#) for more information.

Temperature

The operating temperature range of a seismometer is determined by the temperature coefficient of the mechanics and components in the force-feedback circuit. A vertical seismometer involves

balancing the acceleration due to the effect of gravity on the proof mass against forces supplied by a suspension. The temperature coefficient relates changes in deflection of the proof mass with temperature and so can be expressed in units of ppm (with respect to g_0 the acceleration due to gravity) per $^\circ\text{C}$. A temperature-compensated axis assembly is one in which changes in forces due to thermoelastic coefficients in the suspension cancel deflections due to coefficients of thermal expansion in the rest of the components (Wielandt 2002), such that a displacement transducer would register no movement of the proof mass.

Some broadband seismometers have very wide temperature ranges, encompassing the full range of possible deployment temperatures. Many of the broadband seismometers with the lowest self-noise, however, have operating temperature ranges of $\pm 10^\circ\text{C}$ or less. These seismometers are equipped with a re-centering mechanism which must be activated after the seismometer has been installed in a new vault, ideally after its temperature has stabilized. Just as horizontal sensitivity to tilt determines the tilt range, vertical sensitivity to temperature determines the temperature range.

Even for a sensor operating well within its temperature range, spurious horizontal or vertical output signals can result from tiny changes in temperature. The temperature sensitivity is typically a direct proportionality of equivalent input acceleration to change in temperature.

For a seismometer which is not temperature compensated, the temperature sensitivity is typically dominated by the thermoelastic coefficient of the mainspring, as shown in Fig. 14 (left). The cantilever balances the mass M against the force of gravity g_0 but as the temperature T changes the stiffness of the beam, represented as a spring constant K changes, and the apparent vertical acceleration $\ddot{x}$ changes.

Summing the forces on the mass M in Fig. 14 (left), we find

$$\sum F = -Kx + Mg_0 = M\ddot{x}$$

Principles of Broadband Seismometry,

Fig. 14 Schematic representation of vertical (left) and horizontal (right) temperature sensitivity

And the temperature sensitivity can be modeled as

$$K = K(\Delta T) = K_0(1 + \beta \Delta T)$$

So if the instrument is designed so that at $T = 0$, there is no apparent acceleration $\ddot{x} = 0$ and the deflection is static at x_0 :

$$x_0 = \frac{Mg_0}{K_0}$$

Now if we allow $T \neq 0$, the apparent acceleration is

$$\begin{aligned} \ddot{x} &= g_0 - \frac{x_0}{M} K_0(1 + \beta \Delta T) \\ &= g_0 - g_0(1 + \beta \Delta T) = g_0 \beta \Delta T \end{aligned}$$

Most copper alloys and steels have a thermoelastic coefficient on the order of $\beta = -300 \text{ ppm}/^\circ\text{C}$, the minus sign indicating that the mainspring relaxes with an increase in temperature.

This translates to a requirement for temperature stability of

$$\Delta T_z = \frac{a_{\text{NLNM}}}{|\beta|g_0} \cong 7 \times 10^{-9} \text{ } ^\circ\text{C}$$

A related problem is to measure ground motion on the order of the NLNM in the presence of temperature-generated tilts. This problem is significant both at the level of the seismometer and its subassemblies and at the level of the seismic vault and related superstructures. One way to model this effect is to visualize the sensor as a

platform with legs which either have different temperature coefficients or which are at different temperatures, as shown in Fig. 14 (right). For such a structure, small differentials produce small tilts:

$$\Delta a = \Delta \theta g_0 = (\alpha_1 T_1 - \alpha_2 T_2) \frac{H}{W} g_0$$

For an enclosure made out of a single material, all that matters is the difference in temperature across the structure. For an enclosure made out of steel or aluminum, the thermal coefficient of expansion is on the order of $\alpha = +20 \text{ ppm}/^\circ\text{C}$, with the positive sign indicating that the material expands with an increase in temperature. For the resulting equivalent horizontal acceleration to be less than the NLNM at a 100 s period, if the height is the same as the width, the temperature difference across the enclosure must be less than

$$\Delta T_x = \frac{a_{\text{NLNM}}}{\alpha g_0} \cong 1 \times 10^{-7} \text{ } ^\circ\text{C}$$

Obviously the actual dimensions of the structure can result in this effect being significantly amplified or attenuated, as can the geometry and relative stiffness of the members. Furthermore, it is important to note in both cases that static temperatures are not a problem because the seismometer does not respond to static acceleration. What matters is temperature variation with time, in the band of interest, in this case near 100 s period. Although this model is extremely simplistic, the point is that mechanisms for the conversion of changes in temperature into tilt abound, both inside a seismometer and outside.

Principles of Broadband Seismometry,

Fig. 15 Thermal/electrical filter analogy

Principles of Broadband Seismometry, Fig. 16 Idealized broadband vault

There is a subtle difference between the vertical temperature sensitivity and the horizontal temperature sensitivity of a seismometer. The vertical output of a seismometer is only sensitive to bulk temperature changes; the horizontal outputs are sensitive to differences in temperature across the surface of some part of the enclosure or differences in coefficient of thermal expansion combined with bulk changes in temperature.

The design of a thermal shield against bulk temperature changes is relatively straightforward and can be conceptualized by analogy with electronic circuits as designing a series of cascaded single-time-constant thermal low-pass filters. The design of bulk thermal isolation structures requires a series of concentric shells of thermally

resistive elements and thermally massive elements.

In Fig. 15 the first layer of thermal insulation R_{vault} shields the thermal mass C_{pier} of the pier, the sensor insulating cover R_{cover} shields the thermal mass C_{sensor} of the sensor, and the internal insulation of the sensor $R_{internal}$, if any, shields the thermal mass C_{pier} of the individual axes of the sensor. It is important when designing thermal shields to avoid accidentally including any thermal short circuits which decrease the effectiveness of the shielding. A thermal short circuit or thermal bridge is any path which crosses a thermal insulator and has high thermal conductivity. For example, if the electrical conduit in Fig. 16 was made of metal and therefore thermally conductive, it will act as a thermal short circuit and

degrade the performance of the vault insulation. This could be visualized in the electrical analogy of Fig. 15 as a low-value resistance in parallel with R_{vault} . A seismometer which includes some thermal insulation measures within its pressure vessel will require less external thermal shielding.

Bulk thermal isolation of the type described thus far primarily addresses the thermal sensitivity of the vertical output of a seismometer. Inhibiting thermally generated noise on the horizontal outputs of a seismometer is a different problem.

First, a vault must be free of drafts. At the same time, a fully sealed vault can make the vault respond to pressure with tilt, particularly if the vault is not installed on competent rock. The solution in some cases is to design the vault to have a single point at which it vents, so that the internal and external air pressures are equalized without generating drafts across the floor of the vault.

Second, air convection within the vault must be inhibited. This is done by reducing the power dissipated within the vault, by filling airspace within the vault with some material which inhibits airflow. The design of bulk thermal insulation is subtly different from the design of a shield intended to stop convective airflow. See the section on “[Installation Procedures](#)” below for more detail.

Pressure

A seismometer not contained within a pressure vessel will exhibit strong pressure sensitivity on the vertical output due to buoyancy of the proof mass. Consider a proof mass with a density $\rho_{\text{proof}} = 8 \text{ g/cm}^3$ at a temperature $T_{\text{air}} = 293 \text{ K}$ in dry air with a specific gas constant of $R_{\text{air}} = 287 \text{ J/kg} \cdot \text{K}$ in standard gravity g_0 . For such a seismometer, the vertical sensitivity to air pressure changes due to buoyancy is (Zürn and Wielandt 2007)

$$\alpha_B = \frac{g_0}{P_{\text{air}}} \frac{\rho_{\text{air}}}{\rho_{\text{proof}}} = \frac{g_0}{R_{\text{air}} T_{\text{air}} \rho_{\text{proof}}} = 15 \frac{\text{nm}}{\text{s}^2 \cdot \text{Pa}}$$

In order to be able to measure motions on the order of the NLNM at 100 s period, we need to keep variation in pressure under

$$\Delta P_B = \frac{a_{\text{NLNM}}}{g_0} R_{\text{air}} T_{\text{air}} \rho_{\text{proof}} = 0.006 \text{ mPa}$$

This requirement is stringent enough that if the pressure vessel of a seismometer is compromised, the vertical output will be dominated by this buoyancy effect.

A pressure vessel must be well designed in order to ensure that changes in atmospheric pressure do not produce equivalent horizontal or vertical outputs. Three critical specifications, then, are pressure attenuation of the pressure vessel and the pressure sensitivities of the vertical and horizontal outputs.

For the vertical channel of a seismometer in a pressure vessel, the limiting pressure effect is that due to atmospheric gravitation. Using the Bouguer plate model, in which the atmosphere above a station is modeled as a cylindrical plate having constant density, the gravitational pressure sensitivity due to atmospheric gravitation is (Zürn and Wielandt 2007)

$$\alpha_G = 2\pi \frac{G_0}{g_0} = 0.043 \frac{\text{nm}}{\text{s}^2 \cdot \text{Pa}}$$

Where the universal gravitation constant is $G_0 = 6.67 \times 10^{-11} \text{ N} \cdot \text{m}^2/\text{kg}^2$. This, then, places a design constraint on a pressure vessel for a broadband seismometer: the pressure vessel will deform in response to changes in atmospheric pressure and result in a corresponding vertical acceleration, but the resulting pressure sensitivity should be less than α_G .

With this number in hand, we can reconsider the effect of buoyancy on the pressure vessel. An increase in atmospheric pressure will cause the volume of air inside the pressure vessel to become smaller; the rigidity of the vessel determines how much smaller. In order for the buoyancy effect to be much smaller than that due to the unavoidable effect of atmospheric gravitation, the pressure vessel must attenuate pressure changes by a factor much greater than

$$k_P = \frac{\alpha_B}{\alpha_G} = 340$$

For the horizontal channels of a seismometer, pressure sensitivity arises because atmospheric loading deforms the ground near the seismometer and produces measurable tilts. The level of sensitivity depends on geology and on depth, with shallow installations on unconsolidated sediment having the greatest sensitivity. At the Black Forest Observatory, the vault is 150–170 m below the surface in hard rock, and the measured admittance is typically (Zürn et al. 2007)

$$\alpha_T = 0.3 \frac{\text{nm}}{\text{s}^2 \cdot \text{Pa}}$$

Thus we can set a reasonable limit on the required horizontal pressure sensitivity of a broadband seismometer. When the pressure vessel deforms in response to pressure and causes the horizontal outputs to tilt and exhibit an apparent horizontal acceleration, the resulting pressure sensitivity should be less than α_T .

With both horizontal and vertical pressure sensitivities, a coherence analysis can be used to find a least-squares best-fit to the relative transfer function. This best-fit pressure sensitivity can then be used to correct seismic records for pressure, if a sufficiently sensitive microbarometer is colocated with the seismometer and recorded.

Magnetic

Temperature-compensated materials suitable for mainsprings tend to be magnetic, so inertial sensors tend to be susceptible to magnetic fields. The susceptibility takes the form of direct proportionality of equivalent output acceleration to magnetic field strength.

The magnetic sensitivity of a very broadband seismometer can vary between 0.05 and 1.4 m/s²/T (Forbriger et al. 2010). In order for the magnetic sensitivity of a seismometer to not interfere with measurement of ground motion down to the NLNM at 100 s during a magnetically quiet period, the vertical magnetic sensitivity must be less than

$$\alpha_M = 0.7 \frac{\text{nm}}{\text{s}^2 \cdot \text{T}}$$

For installations which must produce quiet records even during geomagnetic storms, a

magnetic shield can be used. Such shields are typically constructed of a high-permeability metal such as permalloy or mu metal.

Geomagnetic storms are not the only source of low-frequency magnetic fields. Hard drives and solar chargers are two examples of common equipment at seismograph stations which tend to generate interfering signals, and should therefore be located as far as away from the seismometer as is practicable.

As with pressure sensitivity, a best-fit magnetic sensitivity can then be used to correct seismic records for pressure, if a sufficiently sensitive magnetometer is colocated with the seismometer and recorded.

Site Selection

There is no substitute for a geological survey when it comes to site selection.

A site survey provides knowledge of the structures over which the seismometer will be installed. Where possible, seismometers should be installed on bedrock and as far away as possible from sources of cultural noise such as roads, dwellings, and tall structures.

The most important factor to consider in terms of geology is the composition of the uppermost stratum. For example, when the boundary of the uppermost layer is clearly defined as roughly horizontal, the S-wave velocity and thickness of that layer will determine the fundamental resonant frequency at that site. Lower velocities and larger drift thicknesses produce greater site amplification at lower frequencies.

Table 3, reprinted with permission from Trnkoczy (2002), grades site quality according to types of sediments or rocks and gives a sense of how the quality of a site relates to the S-wave velocity.

Low porosity is furthermore important as water seepage through the rock can cause tilts which overwhelm the seismic signal at long periods. Clay soils and, to a lesser extent, sand, are especially bad in this sense.

Principles of Broadband Seismometry,
Table 3 Classification of rock for site selection

Site quality		S-wave velocity (m/s)	
		Min	Max
1	Unconsolidated (alluvial) sediments (clays, sands, mud)	100	600
2	Consolidated clastic sediments (sandstone, marls); schist	500	2,100
3	Less compact carbonatic rocks (limestone, dolomite) Less compact metamorphic rocks; conglomerates, breccia, ophiolite	1,800	3,800
4	Compact metamorphic rocks and carbonatic rocks	2,100	3,800
5	Magmatic rocks (granites, basalts); marble, quartzite	2,500	4,000

Installation Procedures

The question of how to get the best performance out of a seismometer is a very involved topic. In this section the focus will be on broadband seismometers in vault enclosures, and in particular the edges of the usual band of interest, near 100 s period and 10 Hz frequency.

Underground Vaults

The STS-1 defined the limits of ground motion measurement at long periods after it was developed, around 1980. Each component of motion, vertical and horizontals, was detected by a mechanical assembly and controlled by a set of feedback electronics in a separate enclosure.

The advent of the STS-1 was accompanied by the development of systems used to maximize its performance (Holcomb and Hutt 1990). For vertical components, pressure and magnetic shielding was provided for vertical components using a glass bell jar and a permalloy shield, respectively.

Specially designed, so-called “warpless” baseplates prevented pressure-generated tilt noise from contaminating horizontal components. The electronics are housed in a separate enclosure which is not sealed and which can require regular replacement of desiccant to avoid anomalous response characteristics (Hutt and Ringler 2011).

The installation of an STS-1 is a delicate procedure; most of the innovations in the field of broadband seismometry since then have aimed at simplifying this procedure as well as reducing power and overall footprint.

To justify the performance of an STS-1, it is usually necessary to have an underground site in hard rock, something which is expensive to construct and unnecessary for earthquake engineering applications.

Shallow Broadband Vault

An idealized broadband vault design is shown in Fig. 16.

One practical procedure for constructing such a site is as follows. A hole is dug using a backhoe in which a large-diameter plastic tube is placed. A concrete slab is poured at the bottom to serve as a pier for the sensors to rest on. Thermal insulation is added around the sensors, and the digitizer is located in a separate compartment above the sensor. A cover is placed over the tube, and the earth which was dug out to make the hole is backfilled around the tube and tamped down up to the level of the lid. A layer of rigid foam insulation is placed across the lid before piling on the rest of the soil removed in digging the hole for the vault.

This same basic procedure can be tailored to the demands of temporary installations. The seismic vault designed for the “transportable array” of the USArray project (EarthScope 2013), for example, features most of the design elements shown in Fig. 16.

Thermal Insulation

Different thermal insulation components in a broadband vault serve different purposes. The sensor insulating cover serves as bulk insulation and as a breeze cover, and by restricting the airspace around the sensor, it stops convection around the sensor. An insulating layer laid on top of the seismic pier prevents convection-driven air currents from causing the pier to distort as they pass over its surface.

The thick layer of insulation over top of the vault serves to bring the vault closer in temperature to a deeper stratum of the ground. Otherwise,

a low thermal-resistance path from the vault to the surface would exist, and much of the benefit of burying a sensor in terms of thermal stability would be lost. Surface air temperature variation does not penetrate very deep into the ground; the effect of the insulation is to drive isotherms of temperature variation deeper into the ground, as shown approximately in Fig. 16. A rule of thumb for good-quality rigid Styrofoam insulation is that 2.5 cm of insulation provides the same thermal insulation as 30 cm of soil.

Pier Construction

The vault is drawn in Fig. 16 to accommodate a seismic pier which is significantly wider than a typical broadband seismometer plus its insulating cover. The reason for this is that some room must be left for the operator to stand beside the sensor and bend over it to orient the sensor to north, level it, and lock its feet. Vaults can be made significantly smaller if the seismometer is self-leveling, such as a ► [Downhole Seismometer](#), but of course the problem of sensor orientation still needs to be addressed.

The drain shown schematically in Fig. 16 will only be effective if the water table is at or below the depth of the seismic pier. Broadband vaults such as this one are prone to flooding; the surest remedy to this problem is to make use of a seismometer that is designed for submersion (e.g., ► [Downhole Seismometers](#)).

Because of the sensitivity of a broadband seismometer to tilt, the seismic pier should be physically decoupled from the vault wall. The soil at the surface will be constantly shifting due to wind and changes in water content or frost heave. Leaving a gap between the vault wall and the pier prevents such soil motion from being transmitted through the vault wall to the pier and producing measurable tilts.

The concrete for the pier should be made from 50 % Portland cement, 50 % sieved sand, and no aggregate. It should be vibrated to eliminate voids and allowed 24 h to harden before use. The pier must not be reinforced with steel; additional strength is not needed, and the different temperature coefficients would result in detectable tilts and cracking with temperature.

All classes of seismometer benefit from being sited on competent rock because levels of high-frequency (>1 Hz) noise of all kinds are lowest when the seismic wave velocities are highest. Broadband seismometers additionally benefit because hard rock sites are less susceptible to tilt, whether driven by pressure, cultural activity, or other phenomena, and horizontal site noise levels will be dominated by tilt at long periods (<0.1 Hz).

Broadband seismometers often must be sited, however, in areas where bedrock does not come near the surface. In these cases the vault design depicted in Fig. 16 is still useful; instead of pouring concrete, it may be convenient to place a stone block on tamped gravel and use that as a seismic pier.

Thermal Shielding

Seismometer insulation is often implemented on a more or less ad hoc basis. Rigid Styrofoam insulation can be glued or taped together to make flat-faced shaped; large-diameter cardboard tubes lined with fiber wool can also be made.

The “Stuttgart shielding” method used in the German Regional Seismic Network (GRSN) is a much more systematic approach, as shown in Fig. 17, reprinted with permission from Hanka (2002). It includes a thick gabbro baseplate, polished on one side, combined with a large stainless steel cooking pot, which provides pressure shielding to improve on the native pressure sensitivity of the STS-2. Both the outside of the pot and the outer surface of the sensor are wrapped with fiber wool to provide thermal insulation. Sometimes the whole assembly is further wrapped in a thermally reflective “space blanket” to provide additional thermal shielding.

A simplified setup was introduced for the GEOFON program. An aluminum enclosure including a “warpleless” baseplate provides the needed additional pressure shielding. Thermal shielding is provided by a foam rubber insert inside the aluminum enclosure and polystyrol beads outside the enclosure.

Some manufacturers provide thermal shields as accessories to seismometers. The thermal

Principles of Broadband Seismometry, Fig. 17 Thermal and pressure shielding for STS-2 (*left: GRSN, right: GEOFON*)

Principles of Broadband Seismometry, Fig. 18 Thermal shield for Trillium 240

shield for a Trillium 240 is shown in Fig. 18. This cover is made of rigid molded plastic filled with insulating foam. The cover is formfitting – without quite touching the sensor – so that it greatly restricts convective airflow around the sensor, without allowing forces to be transferred to the sensor body through the insulation. It includes a race for a turn of the sensor cable, which minimizes heat conduction through the cable. The shield includes a foam base gasket which raises the cover up off the pier and allows the cable to exit the shield, and provides a layer of insulation between the sensor and the surface of the seismic pier. Such shielding systems are rugged and easy to transport and provide excellent shielding performance and repeatability.

Other Installation Details

Many precautions which must be taken in installing a broadband seismometer should go without saying but must be stated anyway:

- Surface of pier must be clear of debris.
- Pier should be free of cracks, particularly beneath sensor.
- Insulating cover must be close to sensor but must not touch it.
- Adjustable feet must be firmly locked.
- Connectors must not touch insulating cover.
- Cable must be strain-relieved close to the sensor.
- Cable must not touch any other structure between connector and strain relief.

Cabling is an underrated source of excess long-period horizontal noise in vault-type installations. It is recommended to “strain-relieve” the cable to the pier, sometimes by placing a heavy weight on it close to the sensor. If this is not done, thermal expansion or other motion induced in the cable can be transferred to the seismometer, generating tilt. Sensitivity to cable-induced noise is particularly acute with stiff cables; cables designed for flexibility make the whole job much easier.

It is always important to follow the manufacturer’s instructions for sensor installation. Each sensor, for example, will provide different features for physical alignment of the sensor to north.

Downhole and Ocean Bottom

It is well known that site noise decreases with depth. This is the primary motivation for installations in deep, cased boreholes. Two newer techniques, which offer reduced installation costs and an even smaller surface footprint, are posthole and direct-burial installations (Nanometrics 2013). The design of such installations is however beyond the scope of this entry (see ► [Downhole Seismometers](#)).

The ocean bottom, in contrast, is an important environment for seismometer deployment not because of reduced levels of site noise, but because most of the earth is covered by ocean. It is similarly beyond the scope of this entry to treat the relevant installation techniques in detail, except to note some parallels with those used on land. Accurate leveling mitigates coupling of horizontal ground motion into the vertical output. Shallow burial can provide significant shielding from the effects of ocean-bottom currents. Colocated pressure sensors can be used to correct excess noise due to infragravity waves on the vertical. See ► [Ocean-Bottom Seismometers](#).

Summary

A seismometer is a kind of inertial sensor which can detect the smallest ground motions in some frequency band. Broadband seismometers are those which can detect motions which are as small as the background motion at a hypothetical quiet site (as represented by a model such as the NLNM) over a frequency band which extends both above and below the microseismic peak.

A broadband seismometer has much better performance than a passive seismometer of the same physical size. The use of displacement transducers and force feedback results in an instrument with better linearity, lower self-noise, and higher sensitivity at long periods.

A broadband seismometer must be installed in a carefully designed vault to ensure that spurious signals due to tilt driven by temperature and other environmental factors are minimized. A broadband seismometer capable of resolving the NLNM at 100 s should have a vertical

pressure sensitivity less than $\alpha_G = 0.04 \text{ nm/s}^2/\text{Pa}$, a horizontal pressure sensitivity less than $\alpha_T = 0.7 \text{ nm/s}^2/\text{Pa}$, and a magnetic sensitivity less than $\alpha_M = 0.7 \text{ nm/s}^2/\text{T}$.

The construction of an effective broadband seismic vault is described in some detail. Several different kinds of thermal insulation, serving different functions, are required for optimal performance at long periods.

Introduction

This entry provides an overview of probabilistic seismic hazard modeling, which has provided fundamental input to the engineering, planning, insurance sectors, and other fields for over 30 years. In essence probabilistic seismic hazard modeling uses the location, size, and occurrence rate of earthquakes to estimate the frequency or probability of damaging or potentially damaging earthquake motions that may occur at a site. By taking into account the frequency of earthquakes as well as the magnitude, the method captures the contribution to seismic hazard from all relevant earthquakes, from the frequent moderate earthquakes (magnitude $5 \leq M < 7$) to the infrequent large to great earthquakes ($M \geq 7$).

The following sections summarize the history and fundamental steps of probabilistic seismic hazard analysis (PSHA), on which probabilistic

seismic hazard modeling is based, providing example applications, discussing strengths and limitations, and describing current research and future needs.

Probabilistic Seismic Hazard Analysis: History, Method, and Outputs

History

Progression from Deterministic to Probabilistic Seismic Hazard Analysis

Prior to development of PSHA, seismic hazard models were primarily based on deterministic methods, in which a limited number of earthquake scenarios (usually just one or two) are selected as most relevant to the seismic hazard of the site. Based on the estimated magnitude of the scenario earthquake, distance from earthquake to site, and other considerations (e.g., slip type and site conditions), a ground motion is estimated for each scenario. While conceptually simple, deterministic methods do not consider the frequency of earthquakes. This can lead to overestimation of the hazard in the case where a source is associated with a very long recurrence interval. Conversely, ignoring sources that produce more frequent earthquakes of lesser size can lead to underestimation of the hazard. For example, a close moderate magnitude earthquake can produce higher ground motions than a more distant, large magnitude earthquake. Recognition of these deficiencies in deterministically based seismic hazard analysis led to the development of the methods of PSHA.

Development of the Probabilistic Hazard Analysis Framework

The framework for PSHA was first developed by Allin Cornell in the late 1960s (Cornell 1968). The motivation for developing PSHA came from the needs of engineers who must make fundamental trade-offs between the initial cost of designing and building a robust structure and the risk of economic loss due to natural disasters. It is important that engineers have the most accurate understanding of the hazard so they can

evaluate these trade-offs to achieve the optimal balance of cost, performance, and risk. Cornell's approach was to draw on the analogy of design winds or floods (e.g., 100-year flood) and provide engineers with a single ground motion value expressed in terms of return period. Cornell used the location, recurrence behavior, and predicted ground motion of earthquake sources to estimate the frequency or probability of exceeding a ground motion at a particular site or across a region. In this respect he saw PSHA as a way of providing a standardized method for the engineer or scientist to consider all possible earthquake scenarios and associated ground motions and their uncertainties to gain a clearer picture of the hazard for use in design.

Method

The basic four steps undertaken in a PSHA for a site are:

1. *Source definition.* Use geologic data and historical earthquake record to define the locations and dimensions of earthquake sources.
2. *Magnitude-frequency relationship.* Define the likely magnitudes of earthquakes that may be produced by each source and the associated frequencies of occurrence.
3. *Ground motion prediction.* Estimate the ground motion level that a source will produce at the site.
4. *Probability of exceedance calculation.* Quantify the frequency or probability at which a ground motion level is exceeded at the site, given all sources. Repeating this procedure for all sources and ground motion levels results in a hazard curve.

These steps are represented graphically in Fig. 1 and described in more detail in the following sections.

Source Definition

Seismicity catalogues, active fault data, and increasingly geodetic strain rates derived from global positioning system (GPS) data are used to define the locations and recurrence behavior of earthquake sources relevant to the site of

Probabilistic Seismic Hazard Models,

Fig. 1 The four steps of probabilistic seismic hazard analysis (After Cornell 1968)

interest. There are two seismic source classes: areal source zone, also referred to as a background or distributed seismicity source (Fig. 1) and fault source. Sources within 100–200 km from the site are usually considered in a PSHA, as sources beyond these distances generally produce ground motions that are too low to be of interest to engineering design.

Areal source zones are used to model the seismicity that is recorded in seismicity catalogues and, in particular, the seismicity that occurs away from known fault sources (e.g., Abrahamson 2011). The most important function of areal sources is therefore to represent sources that lack surface expression and have escaped detection by geologists. Areal source zones actually represent crustal volumes, as they are defined by a geographic area and an assumed thickness based on the maximum depth of seismicity (the seismogenic thickness). Fault sources are commonly modeled as planar features with length and depth that are based on surface fault traces and subsurface information.

Magnitude and Frequency

For fault sources, the dimensions and slip rate and/or paleoseismic (prehistoric) data defining the recurrence behavior of each source is used to develop a magnitude-frequency distribution of earthquakes. The distribution can range from a single magnitude and associated frequency (usually referred to as a characteristic earthquake; Schwartz and Coppersmith 1984) to a range of magnitudes. In the case of the characteristic earthquake, the magnitude is determined by the general equation

$$M_w = \log(A) + b, \quad (1)$$

where A is the fault area and b is a constant that is controlled by factors such as fault type, geology, regional tectonics, and stress drop. Various forms of the equation exist for different fault types and tectonic environments (e.g., Stirling et al. 2013), and there are also relationships that use the length of the fault to determine magnitude.

For areal sources, a range of earthquakes are usually considered for the source, utilizing the well-established Gutenberg-Richter relationship:

$$\text{Log}N(M) = a - bM, \quad (2)$$

where $N(M)$ is the activity rate, M is the magnitude, and a and b are empirical constants. The relationship was found to describe the seismicity of regions across the globe (Gutenberg and Richter 1944). The b -value is typically around 1, which means that there is roughly a tenfold decrease in the number of earthquakes between magnitude M and $M + 1$. The Gutenberg-Richter distributions are typically defined from seismicity catalogue data, and occasionally GPS and geologic data are used as well.

Ground Motion Model

Ground motion prediction equations (GMPEs), formerly called attenuation relations, are used to model the attenuation of ground motions with distance from the source. Various GMPEs have been developed for different tectonic regions (Abrahamson 2011). GMPEs typically account for magnitude, type of faulting, distance from the source, site response, and number of standard deviations. In PSHA the probability that the ground motion S_a exceeds the test value (z) is calculated for each magnitude (M) distance (r), and number of standard deviations (ε).

$$P(S_a > z | M, r, \varepsilon) \quad (3)$$

GMPEs have been developed for shallow crustal earthquakes in active tectonic regions (e.g., California), shallow crustal earthquakes in stable continental regions (e.g., eastern North America), and subduction zone earthquakes (e.g., Japan), rift environments, and others. The most recent suite of GMPEs has been produced by the PEER Next Generation Attenuation project (PEER-NGA; <http://peer.berkeley.edu/ngawest>). Over time, GMPEs have progressed from being developed for global application to being more focused on tectonic regimes and geographical regions (e.g., New Zealand; McVerry et al. 2006).

Probability of Exceedance Calculation

The final step of PSHA is to develop a hazard curve (Step 4 in Fig. 1), which gives the frequency or probability of exceedance for a suite of ground motion levels. The following equation is the fundamental equation of PSHA that produces the hazard curve:

$$v_i(S_a > z) = N_i(M_{\min}) \int_{r=0}^{\infty} \int_{M_{\min}}^{M_{\max}} \int_{\varepsilon_{\min}}^{\varepsilon_{\max}} f_{m_i}(M) f_{r_i}(r) f_{\varepsilon}(\varepsilon) P(S_a > z | M, r, \varepsilon) dr dM d\varepsilon \quad (4)$$

where $v_i(S_a > z)$ is the annual rate of events (v_i) on a single source that produce a ground motion parameter (S_a) exceeding a specified level (z) at the site of interest. The inverse of v is the return period in years. The hazard is therefore the integration over all possible magnitudes ($f_{m_i}(M)$), distances from the site to the source ($f_{r_i}(r)$), and standard deviations ($f_{\varepsilon}(\varepsilon)$). The ground motion for each individual scenario is calculated using a GMPE and the probability that the ground motion exceeds the test level is calculated (see “Ground Motion Model”).

PSHA is fundamentally a bookkeeping exercise. Instead of developing a small number of deterministic scenarios, a probabilistic seismic hazard model may develop many thousands of scenarios, each with relative contributions to the overall hazard at the site of interest. The rates of ground motions that exceed the specified level z are summed up over all sources to determine how often severe shaking occurs at a site, regardless of the source of the ground motion.

Outputs

Hazard Curve

The hazard curve (Step 4; Fig. 1) gives a suite of ground motion levels and their associated frequencies or return periods. A ground motion level is therefore read off the hazard curve at a user-specified annual frequency, and an important part of the probabilistic seismic hazard modeling process is selecting the appropriate

Probabilistic Seismic Hazard Models, Fig. 2 Procedure for developing uniform hazard spectra. In this example a return period of 475 years is used (Abrahamson 2011)

hazard level or return period. The return periods considered for engineering designs typically range from 475 years (often considered for ordinary buildings) to 2,500 years (special buildings, such as hospitals), which are, respectively, equivalent to 10 % and 2 % probability of exceedance in 50 years (e.g., Stirling et al. 2012). In contrast, nuclear facilities and major hydro-dam developments typically consider hazard estimates with 10,000-year return periods or longer. Hazard estimates for these three return periods typically show large quantifiable differences across regions like the USA, Europe, Japan, and New Zealand, reflecting the long-term tectonically driven differences in the expected future activity of earthquake sources across the regions.

Uniform Hazard Spectra

Uniform hazard spectra, or equal hazard spectra (Fig. 2), can be rapidly developed from a probabilistic seismic hazard model to provide seismic design loadings for a range of return periods and spectral periods. The hazard curve (Step 4 in Fig. 1) is plotted for a suite of different spectral periods. At a chosen annual frequency or probability, the spectral acceleration (S_a) for each spectral period is measured from the hazard curve and plotted on a separate graph (Fig. 2). Spectral shapes differ for different sites due to local soil

conditions and the different mixes of earthquake magnitudes and distances surrounding the site of interest. The spectra therefore provide meaningful site-specific input to design loadings, including the selection of design earthquake scenarios and associated time histories (actual recordings of earthquakes used in engineering analysis). A response spectrum can also be plotted for a real event (Fig. 3) or a scenario event.

Deaggregation

Because the hazard curve is an ensemble of sources, magnitudes, and distances, it can be difficult to understand the relative contributions to the hazard at a site (Abrahamson 2011). The hazard curve can be broken down, or deaggregated, by magnitude and distance to identify the relative contribution of different earthquake scenarios to the hazard at a site. Similar scenarios are grouped together and the fractional contribution of different scenario groups to the hazard is computed and plotted on a deaggregation graph (Fig. 4). The results of the deaggregation will differ for different return periods and spectral periods. The deaggregation plots are often used to select realistic time histories for input to seismic loading analysis and to design scenario earthquakes for territorial authorities and others to plan for future earthquakes.

Probabilistic Seismic Hazard Models, Fig. 3 Examples of response spectra for Christchurch, New Zealand, for deep soil site conditions. The *solid lines* are spectral accelerations (SAs) recorded at selected strong motion stations in the city during the M6.2 2011 Christchurch

earthquake, and the *dashed line* is a response spectra derived from the New Zealand national seismic hazard model for a 10,000-year return period (Figure courtesy of Graeme McVerry, GNS Science)

Probabilistic Seismic Hazard Models, Fig. 4 Example of a deaggregation for the city of Christchurch derived from the New Zealand national seismic hazard model (Stirling et al. 2012). The deaggregation plot identifies two relevant classes of earthquakes that dominate the hazard of the city: earthquakes of M5-6.0 at distances of less than 10 km to the city and M6.0-7.5 at distances of 10–50 km. These classes of earthquakes encompass all of the major earthquakes of the Canterbury 2010–2012 earthquake sequence, despite the model being developed prior to initiation of the sequence

Example Applications

Regional, National, and Global Hazard Maps

PSH maps of regions, countries, and the globe are routinely produced by the PSHA process (Fig. 5) at a grid of sites, and then the results are mapped for a given return period. The GSHAP (Global Seismic Hazard Analysis Program, the predecessor of the Global Earthquake Model GEM; globalquakemodel.org) map in Fig. 5a is an example of a global PSH map, which was developed to understand the global distribution of seismic hazard.

Two examples of national-scale PSH maps are from New Zealand (Fig. 5b) and the USA (Fig. 5c). These maps show high hazard along the main plate boundary areas and lower hazard away from the plate boundaries and provide very useful information for engineering and planning, including the development of design standards such as the New Zealand Loadings Standard NZS1170.5 (Standards New Zealand 2004).

At a regional scale, an example from the San Francisco Bay Area is shown in Fig. 6a, b. These

Probabilistic Seismic Hazard Models, Fig. 5 (continued)

Probabilistic Seismic Hazard Models, Fig. 5 Examples of global and national PSH maps: (a) Global seismic hazard analysis program (GSHAP) model (Giardini et al. 1999), (b) New Zealand national seismic hazard

model (Stirling et al. 2012), and (c) US national seismic hazard model (Petersen et al. 2008). Each map shows the peak ground accelerations (PGA) expected for a 475-year return period on soft rock sites

PSH maps were developed for use by the public and local governments to help drive hazard mitigation decision-making and policy with appropriate understanding of the likelihood of a significant earthquake event and the expected intensity. The PSHA map was deaggregated across a grid of the region to show the scenario with the highest contribution to the hazard in each location. The deaggregation map provides a guide for selecting the most appropriate earthquake scenarios for a given region or location. Scenario maps are available online for each of the major hazard sources identified in the deaggregation (quake.abag.ca.gov/earthquakes). A legend was developed that links MM (Modified Mercalli) intensity (the earthquake shaking intensity scale that is measured according to its effect on people, objects, and buildings) to expected nonstructural and structural damage of common dwelling types. In this way mitigation decisions by the public are risk informed and appropriate for the expected hazard (Brechwald and Mieler 2013).

Site-Specific Seismic Hazard in Wellington, New Zealand

New Zealand's capital city has long been a focus of site-specific PSHAs in New Zealand. The Wellington region is crossed by a number of major right lateral strike-slip faults and is underlain by the west-dipping subduction interface between the Pacific Plate and overriding Australian Plate (Hikurangi subduction zone) (Holden et al. 2013). In the short historic period of European settlement (ca. 160 years), the region has been shaken by large earthquakes, the largest being the M8.1-8.2 1855 Wairarapa earthquake. This earthquake also stands as the largest historical earthquake to have occurred in New Zealand since European colonization began in 1840. The earthquake was felt over a large part of the North Island and South Island of New Zealand and was severely damaging to settlements in the southern half of the North Island, particularly Wellington and Wanganui (Fig. 7).

Hazard curves for Wellington from the national seismic hazard model (Stirling

et al. 2012) are shown for several spectral periods in Fig. 8., The change in hazard as a function of return period is also illustrated by the two peak ground acceleration (PGA) hazard maps in Fig. 9a, b and by graphs of site-specific response spectra for Wellington city (Fig. 10). The highest overall spectrum is associated with the longest return period.

Wellington's 475-year PGA and S_a 1.0 s deaggregation are shown in Fig. 11a, b, respectively. The 475-year PGA hazard is dominantly controlled by fault sources. Peaks on the deaggregation plots show high contributions to overall hazard from the Wellington Fault

(M7.5 at less than 1 km; 20 % contribution), Ohariu Fault (M7.6 at 5 km; 20 % contribution), and Wairarapa Fault (M8.1 at 17 km; 13 % contribution). The 475-year S_a 1.0 s graph for Wellington shows an additional contribution to hazard from the local subduction zone (M8.1-9.0 at 23 km; 20 % contribution).

Limitations of Probabilistic Seismic Hazard Models

Recent, devastating earthquakes like the M9.0 2011 Tohoku, Japan, and M6.2 2011

Probabilistic Seismic Hazard Models, Fig. 6 (continued)

Probabilistic Seismic Hazard Models, Fig. 6 (a) PSH map for the San Francisco Bay Area, California, shown as an example of a regional-scale hazard map. MMI map obtained from 10 % probability in 50-year PGV values (equivalent to 475-year return period) (Brechtwald and

Mieler 2013). (b) Deaggregation of 10 % in 50-year hazard (a), showing fault scenario with most significant contribution to hazard by location (Brechtwald and Mieler 2013)

Christchurch earthquakes have resulted in considerable criticism of PSHA (e.g., Stein et al. 2011). The most frequent criticism is that PSHA did not provide any warning that these events were going to occur in 2011. While this is indeed the case, it is also correct to say that PSH models were never designed to provide short-term earthquake forecasts. The accelerated needs in Japan, New Zealand, and elsewhere to find short-term forecasting solutions are clearly beyond what standard PSHA can provide. Short-

term forecasting requires construction of time-dependent or “time-varying” probability models. These models logically require two types of data: (1) detailed knowledge of the earthquake history and prehistory of well-studied faults, so the earthquake recurrence interval and elapsed time since the last earthquake faults can be determined, and (2) high-quality earthquake catalogues, which allow earthquake clustering behavior to be deciphered and modeled with time-varying rate or probability models (e.g., Rhoades et al. 2010).

Probabilistic Seismic Hazard Models, Fig. 7 Isoseismal map for the 1855 Wairarapa earthquake (maximum intensity MM9, possibly MM10; Downes and Dowrick 2009)

Probabilistic Seismic Hazard Models,

Fig. 8 Example of hazard curves as a result of a PSH analysis for the city of Wellington (data from the Stirling et al. 2012)

Probabilistic Seismic Hazard Models, Fig. 9 Seismic hazard maps for 475- and 2,500-year return periods (10 % and 2 % probability of exceedance in 50 years)

for class C (shallow soil) site conditions: (a) peak ground acceleration (PGA) for 475-year return period; (b) PGA for 2,500-year return period (Stirling et al. 2012)

However, the resulting models generally differ greatly in terms of the resulting probabilities, and no one model is presently capable of providing a prospective short-term forecast of a large earthquake sequence that suddenly occurs in an area of low seismicity or seismic quiescence (as was the case for the Canterbury earthquake

sequence). The ability to provide actual short-term earthquake forecasts in areas of low seismicity still requires some significant advances in relevant scientific research and monitoring/detection.

Ground motion prediction (Step 3 of Fig. 1) is the source of large uncertainties for PSHA.

Probabilistic Seismic Hazard Models, Fig. 10 Response spectra for Wellington city for 150, 475, 1,000, and 2,500 years for class C (shallow soil) site conditions (Stirling et al. 2012). *Dashed lines* show the Stirling et al. (2002) spectra for comparison

Probabilistic Seismic Hazard Models, Fig. 11 Deaggregation graphs for the city of Wellington for (a) 475-year PGA for class C (shallow soil) site conditions and (b) 475-year SA 1 s to show the contribution of Hikurangi subduction interface sources at longer spectral periods (Stirling et al. 2012)

GMPEs are typically associated with large standard deviations (about 0.5 in natural log units of ground motion), which represents aleatory (random) uncertainty. Therefore, two earthquakes of the same magnitude and occurring the same distance away from a site can produce hugely different levels of shaking for unknown reason. These ground motion standard deviations do not appear to be reducing despite successive updates of ground motion prediction equations

(e.g., Watson-Lamprey 2013). In the Christchurch earthquake, PGAs of over 2 g were produced at some strong motion stations during the earthquake, and this was greatly in excess of what would normally be expected for an earthquake the size of the Christchurch earthquake (M6.2). Another issue associated with probabilistic seismic hazard models is that earthquakes often occur on sources that were previously unidentified. The causative fault of the main

shock of the Canterbury earthquake sequence (the M7.1 2010 Darfield earthquake) was unknown prior to the earthquake on 4 September 2010 due to the long recurrence interval and resulting lack of topographic expression of the fault in the relatively young Pleistocene outwash surface defining the Canterbury Plains. In the national seismic hazard model for New Zealand (Stirling et al. 2012), the earthquake was to some extent accounted for by the areal source model (i.e., consistent in terms of the long-term recurrence interval for Darfield-sized events), but these models do not inform where the earthquake sources and strongest shaking will occur and when the sources will produce the earthquakes. Again, this is an area of science that needs major advances in understanding and monitoring the changes that lead up to the occurrence of a large earthquake.

New Developments

Ground Motion Prediction

Many new GMPEs have been developed in the last decade, capturing the rich strong motion datasets produced by earthquakes in well-instrumented areas (e.g., Taiwan). The PEER-NGA project has involved some of the world's key GMPE developers producing a suite of GMPEs from the same quality-assured strong motion dataset. The models have incorporated more input parameters in an effort to improve ground motion prediction, particularly with respect to source geometry.

Improved Monitoring

Efforts to improve the recording of input data by seismic and GPS networks are of fundamental importance to PSHA. Seismic networks (e.g., Geonet in New Zealand, <http://geonet.org.nz>) are making large improvements to the detection threshold of earthquakes (the minimum magnitude for a complete record of earthquakes) and the ability to observe temporal and spatial changes in seismicity. GPS is being increasingly used to provide input to source models (e.g., distributed seismicity models and subduction

interface models). The generally short temporal coverage of GPS data is compensated for by a large spatial coverage, and as such it can provide a compliment to other source models. Satellite interferometry is another technique that is showing improvements in applicability and resolution over time, and these will allow greater ability to detect the coseismic deformation field (closely related to the source dimension) from earthquakes.

Detection and Characterization of Active Faults

Active fault datasets are the only PSHA input datasets that are able to extend the earthquake record back in time to prehistory. Great improvements in the ability to detect and characterize active faults for input to probabilistic seismic hazard models have been seen in the last 10 years. Fault mapping has improved significantly through accumulated experience and the availability of new tools (e.g., LIDAR). Greater ability to map the surface geometry of faults and distributions of displacement has led to improved characterization of fault sources in PSH models. The use of different disciplines and datasets together for fault characterization, particularly with respect to mapping fault ruptures in three dimensions, has yielded a great deal of understanding of rupture complexity and detail. Furthermore, increased age control on paleoearthquakes has made it possible to establish conditional probabilities of future ruptures and associated uncertainties.

Supercomputing to Consider All Possibilities

PSH models are increasingly drawing on diverse datasets and methods and utilizing high-end computing resources. The UCERF3 model (wgcep.org) incorporates hundreds of thousands of logic tree branches in its comprehensive source model, and access to supercomputers allows the complex model to be run through the four steps of PSHA (Fig. 1). Furthermore, physics-based seismic hazard modeling efforts such as CyberShake (SCEC.org) utilize supercomputers to run multiple realizations of earthquake scenarios from multiple sources, with shaking at the site computed

directly from source, path, and site effects for each earthquake. The millions of calculations required would not be possible without access to major computing resources and would not have been possible as recently as a decade ago. Plausible scenarios such as the linking of fault sources to produce extended ruptures and the range of uncertainties in magnitude-frequency statistics for the myriad sources are able to be handled without consideration of CPU demand. Already, exciting scientific results have emerged from the UCERF3 modeling efforts, such as the finding that seismicity on faults may not be well modeled by the Gutenberg-Richter relationship, as this produces a poor fit to the paleoseismic data in California (Ned Field pers. comm. 2013).

Future Needs

Correct Use of PSH Models

Many of the criticisms of PSHA in recent literature have been due to PSH models being used beyond their design capabilities. The models are not designed to be used as short-term forecasting tools, but more appropriately used to estimate seismic hazard for long return periods. The PSH models are also only as good as the input data and generalized methods of source parameterization, ground motion estimation, and probability estimation. However, as long as the associated uncertainties and limitations are fully expressed in the model commentary and appropriate cautionary advice is provided to the end users, the models will continue to provide valuable information. Use of deterministic models and appropriate parameterization of areal source models are two examples of solutions used to compensate for known or suspected deficiencies in PSH models.

Some recent efforts have focused on providing scientific forums to openly debate some of the criticisms leveled at PSHA and the associated input. The American Geophysical Union and Seismological Society of America have held "Earthquake Debates" sessions on several occasions over the last 5 years. Furthermore, the Powell Center for Analysis and Synthesis (<http://powellcenter.usgs.gov/>) has recently supported

a series of workshops that have brought together PSHA experts and critics from around the world, face to face, to address issues associated with maximum magnitude estimation, testability of PSHA, and development of global seismic source models (<http://www.nexus.globalquakemodel.org/powell-working-group/>). These meetings have been very productive, as people have been working together on common ground rather than talking past each other in the literature.

Earthquake Forecasting Without Earthquake Sequences

Clearly, a major advance in earthquake hazard estimation would be to achieve reliable short-term earthquake forecasts in areas of low seismicity, or in areas experiencing extended periods of seismic quiescence. To this end, future research needs to be focused on improving the ability to monitor and detect microseismicity and crustal deformation and on identifying reliable earthquake precursors. The Canterbury earthquake sequence has resulted in considerable advances being made in the modeling of short-term earthquake probabilities post-mainshock (i.e., aftershocks). These lessons are now being applied to the rebuilding of the city of Christchurch and will be applied to the rest of the country in the coming years. Clearly, these efforts need to be complimented with efforts to identify short-term precursors of future earthquakes in areas that are seismically quiet.

Reduction in Aleatory Uncertainty in Ground Motion Prediction

The aleatory uncertainty in ground motion estimation is very large and does not seem to have been reduced by the increasingly complex GMPEs available today. In other words there is still a very large range in the potential ground motions that could be produced at a single site due to earthquakes of the same magnitude, distance, and slip type. In contrast, the differences between GMPEs (epistemic uncertainties) do appear to have been reduced in recent years, at least within the NGA project. Clearly, effort needs to be focused on better understanding the source, path, and site effects that lead to the large

differences in ground motions observed in the strong motion databases.

Testability of Probabilistic Seismic Hazard Models

Finally, efforts need to be supported in the objective testing of PSH models, as to date PSH models have largely been developed in the absence of any form of verification. The Collaboratory for the Study of Earthquake Predictability (CSEP) has been developing testing strategies and methods for a wide variety of applications (SCEC.org), and collaborative work has also been focused on developing ground motion-based tests of the New Zealand and US national seismic hazard models. The Global Earthquake Model (GEM) Foundation (globalquakemodel.org) is including testing and evaluation as an integral part of the overall model development. The Yucca Mountain seismic hazard modeling project developed innovative approaches to consider all viable constraints on ground motions for long return periods for nuclear waste repository storage, prior to cancellation of the project in 2008 (Hanks et al. 2013). The need to verify hazard estimates for return periods of 10^4 – 10^6 years advanced the use of geomorphic criteria such as fragile geologic features (FGFs) to test the hazard estimates. The rationale is that these FGFs provide evidence for non-exceedance of ground motions for long return periods.

Complex PSHA on Normal Computers

If the future of PSHA is in the development of complex PSH models such as UCERF3, the reliance of these models on supercomputer resources will be a significant barrier to the widespread utility of these models and methods. Significant efforts in the future will therefore need to be focused on making these models usable on standard computers, or uptake will be extremely limited for everyday end-user PSHA applications.

Summary

This entry provides an overview of probabilistic seismic hazard (PSH) models which have provided fundamental input to the engineering,

planning, insurance sectors, and other fields for over 30 years. In essence PSH models use the location, size, and occurrence rate of earthquakes to estimate the frequency or probability of damaging or potentially damaging earthquake motions that may occur at a site. By taking into account the frequency of earthquakes as well as the magnitude, the models capture the contribution to seismic hazard from all relevant earthquakes, from the frequent moderate earthquakes (magnitude $5 \leq M < 7$) to the infrequent large to great earthquakes ($M \geq 7$). The entry summarizes the history and fundamental steps of PSHA, provides example applications, discusses strengths and limitations of PSHA, and describes current research and future needs.

Introduction

The seismic ground motions are well recognized to be stochastic processes for over 60 years. Under such extreme loadings with large uncertainty, it is almost impossible for engineering structures subjected to earthquakes to avoid nonlinear behaviors during their service life (Roberts and Spanos 1990). Simultaneously, large uncertainties also exist in the models of structures, including the system mechanics parameters and such factors as non-structure effects, boundary conditions, geometric sizes, etc. For instance, the strength of concrete usually has a coefficient of variation (COV)

from 10 % to 23 %, whereas even the strength of steel, which is thought to be much more homogeneous, has a COV ranging from 7 % to 9 %. This may induce the fluctuation of static response of structures in the same order of magnitude of COV of the source uncertain parameters. However, the fluctuation in dynamic response may be enlarged greatly. In addition, the coupling of randomness in the system parameters and excitations will make the fluctuation of response much greater than that of response when the randomness is involved only in excitations (Chen and Li 2010). Therefore, to consider the randomness involved in both system parameters and excitations together with their coupling with the development of nonlinearity in structural behaviors is of paramount importance.

Engineering stochastic dynamics has been developed for over half a century, exhibited as two branches, i.e., the random vibration theory and stochastic structural analysis (stochastic finite element method). For linear structures, in both branches the probabilistic information of the second-order statistics could be well obtained (Ghanem and Spanos 1991; Li 1996). In random vibration when the excitations are white noise processes, the joint probability density function (PDF) is governed by the FPK equation, and the solution is well known as a joint Gaussian distribution. But in stochastic structural analysis, where the uncertainty of system parameters is dealt with, no analogous partial differential equation exists in the traditional theory (Li 1996; Ghanem and Spanos 1991). Moreover, in both random-parameter problems and random-excitation problems, huge difficulty exists in dealing with multi-degree-of-freedom (MDOF) nonlinear structures (Goller et al. 2013; Zhu 2006). The coupling of nonlinearity and randomness in MDOF systems is almost unbreakable. This is the common crucial difficulty in both branches.

In the past decade, a family of probability density evolution method (PDEM) was developed. In this method, the thought of physical stochastic systems was advocated (Li and Chen 2009). The principle of preservation of probability was adopted as a unified basis and revisited from the state space description and the random event

description (Li and Chen 2008). A decoupled generalized density evolution equation was derived and solved together with the embedded physical equations. By this the instantaneous PDF and reliability of MDOF nonlinear structures with randomness involved in both system parameters and external loadings could be captured (Li and Chen 2003, 2005; Chen and Li 2005; Li et al. 2012a; Goller et al. 2013). This entry will outline its theoretical basis and numerical algorithms and particularly put emphasis on earthquake engineering applications.

Basic Principles of the Probability Density Evolution Method

Without loss of generality, the equation of motion of an n -DOF structure subjected to seismic ground motion is

$$\mathbf{M}(\boldsymbol{\eta})\ddot{\mathbf{X}} + \mathbf{C}(\boldsymbol{\eta})\dot{\mathbf{X}} + \mathbf{f}(\boldsymbol{\eta}, \mathbf{X}) = -\mathbf{M}(\boldsymbol{\eta})\mathbf{I}a_R(\boldsymbol{\xi}, t) \quad (1)$$

where $\ddot{\mathbf{X}}, \dot{\mathbf{X}}, \mathbf{X}$ are the n -dimensional vectors of acceleration, velocity, and displacement relative to ground, respectively; $\mathbf{M}$ and $\mathbf{C}$ are the n by n mass and damping matrices, respectively; $\mathbf{f}$ is the linear or nonlinear restoring forces; $\mathbf{I}$ is the n -dimensional column vector with all components being 1, $a_R(\boldsymbol{\xi}, t)$ is the ground motion accelerogram, which could be specified by the models to be outlined in the later section; $\boldsymbol{\eta} = (\eta_1, \dots, \eta_{s_1})$ are the basic random parameters in the structural system properties; and $\boldsymbol{\xi} = (\xi_1, \dots, \xi_{s_2})$ are the basic random parameters in the excitation. For notational convenience, let $\boldsymbol{\Theta}(\varpi) = [\Theta_1(\varpi), \dots, \Theta_s(\varpi)] = (\boldsymbol{\eta}, \boldsymbol{\xi}) = (\eta_1, \dots, \eta_{s_1}, \xi_1, \dots, \xi_{s_2})$, where $s = s_1 + s_2$.

If the state vector $\mathbf{Y} = (\mathbf{X}^T, \dot{\mathbf{X}}^T)^T = (Y_1, \dots, Y_{2n})^T$ is introduced, Eq. 1 could be rewritten as a stochastic state equation:

$$\dot{\mathbf{Y}} = \mathbf{A}(\mathbf{Y}, \boldsymbol{\Theta}(\varpi), t) \quad (2)$$

where $\mathbf{A} = (A_1, \dots, A_{2n})^T = \left(\dot{\mathbf{X}}^T, [-\mathbf{M}^{-1}\mathbf{C}(\boldsymbol{\eta})\dot{\mathbf{X}} - \mathbf{M}^{-1}\mathbf{f}(\boldsymbol{\eta}, \mathbf{X}) - \mathbf{I}a_R(\boldsymbol{\xi}, t)]^T \right)^T$. The initial condition is given by $\mathbf{Y}(0) = \mathbf{Y}_0$.

Let us consider the PDF of $Y_\ell(t)$, the ℓ -th component of $\mathbf{Y}(t)$. Denote the PDF by $p_{Y_\ell}(y, t)$. To understand the evolution of $p_{Y_\ell}(y, t)$, consider the change of probability in an arbitrary interval $[y_L, y_R]$ during the time interval $[t, t + \Delta t]$:

$$\begin{aligned} \Delta P_D &= \int_{y_L}^{y_R} p_{Y_\ell}(y, t + \Delta t) dy - \int_{y_L}^{y_R} p_{Y_\ell}(y, t) dy \\ &= \left(\int_{y_L}^{y_R} \frac{\partial p_{Y_\ell}(y, t)}{\partial t} dy \right) \Delta t + o(\Delta t) \end{aligned} \quad (3)$$

This portion of change of probability is due to the probability transiting through the boundaries y_L and y_R . If during per unit time the probability passing a point z could be denoted by $J(z, t)$, then the change of probability in $[y_L, y_R]$ during $[t, t + \Delta t]$ is given by

$$\begin{aligned} \Delta P_B &= -J(y_R, t)\Delta t + J(y_L, t)\Delta t + o(\Delta t) \\ &= - \left(\int_{y_L}^{y_R} \frac{\partial J(y, t)}{\partial y} dy \right) \Delta t + o(\Delta t) \end{aligned} \quad (4)$$

According to the principle of preservation of probability, $\Delta P_D = \Delta P_B$. Substituting Eqs. 3 and 4 in it and considering the arbitrariness of $[y_L, y_R]$ yield

$$\frac{\partial p_{Y_\ell}(y, t)}{\partial t} = - \frac{\partial J(y, t)}{\partial y} \quad (5)$$

This is nothing but the continuity equation, in which $J(y, t)$ is the flux of probability, i.e., the probability passing a point during per unit time. According to this physical meaning, the flux of probability is $J(y, t) = \lim_{\Delta t \rightarrow 0} \frac{\Delta P_y}{\Delta t}$, where ΔP_y is the probability passing the point y during Δt , i.e., $\Delta P_y = p_{Y_\ell}(y, t)\Delta y + o(\Delta y)$, in which Δy is the displacement of the particle during Δt . Note that both $Y_\ell(t)$ and $\dot{Y}_\ell(t)$ depend on $\Theta(\omega)$. There is

$$\begin{aligned} \Delta P_y &= p_{Y_\ell}(y, t)\Delta y + o(\Delta y) \\ &= \int_{\Omega_\Theta} \left[\Delta Y_\ell(\boldsymbol{\theta}) p_{Y_\ell|\Theta}(y, t|\boldsymbol{\theta}) \right] p_\Theta(\boldsymbol{\theta}) d\boldsymbol{\theta} + o(\Delta y) \\ &= \left(\int_{\Omega_\Theta} [\dot{Y}_\ell(\boldsymbol{\theta}, t) p_{Y_\ell|\Theta}(y, \boldsymbol{\theta}, t)] d\boldsymbol{\theta} \right) \Delta t + o(\Delta t) \end{aligned} \quad (6)$$

where $p_{Y_\ell|\Theta}(y, t|\boldsymbol{\theta})$ is the conditional PDF and $p_{Y_\ell|\Theta}(y, \boldsymbol{\theta}, t)$ is the joint PDF of $(Y_\ell(t), \Theta)$. Clearly,

$$p_{Y_\ell}(y, t) = \int_{\Omega_\Theta} p_{Y_\ell|\Theta}(y, \boldsymbol{\theta}, t) d\boldsymbol{\theta} \quad (7)$$

According to Eq. 6,

$$J(y, t) = \lim_{\Delta t \rightarrow 0} \frac{\Delta P_y}{\Delta t} = \int_{\Omega_\Theta} [\dot{Y}_\ell(\boldsymbol{\theta}, t) p_{Y_\ell|\Theta}(y, \boldsymbol{\theta}, t)] d\boldsymbol{\theta} \quad (8)$$

Substituting Eqs. 7 and 8 in Eq. 5 yields

$$\begin{aligned} \frac{\partial}{\partial t} \int_{\Omega_\Theta} p_{Y_\ell|\Theta}(y, \boldsymbol{\theta}, t) d\boldsymbol{\theta} &= \\ - \frac{\partial}{\partial y} \int_{\Omega_\Theta} [\dot{Y}_\ell(\boldsymbol{\theta}, t) p_{Y_\ell|\Theta}(y, \boldsymbol{\theta}, t)] d\boldsymbol{\theta} \end{aligned} \quad (9)$$

which should hold for any arbitrary domain Ω_Θ , and therefore the integrand should be identical, i.e.,

$$\frac{\partial p_{Y_\ell|\Theta}(y, \boldsymbol{\theta}, t)}{\partial t} = -\dot{Y}_\ell(\boldsymbol{\theta}, t) \frac{\partial p_{Y_\ell|\Theta}(y, \boldsymbol{\theta}, t)}{\partial y} \quad (10)$$

This is the generalized density evolution equation (GDEE). More rigorous derivation could be found in Li and Chen (2008, 2009) and Chen and Li (2009).

Remark 1 The most important advantage of GDEE compared to the traditional equations, e.g., the FPK equation, is that the dimension is totally untied from the original dynamical system. Actually, although Eq. 10 is in one dimension, from the above heuristic deduction process, it is clear that if any arbitrary number of

components are of concern, a corresponding GDEE in appropriate dimensions exists.

Remark 2 In the PDEM there is no need for the stochastic process of concern to be Markovian. Actually, in most cases the process is not Markov. For instance, in engineering practice a complex structure may be modeled by the finite element method where nonlinear constitutive relationship of the material, say, the stochastic damage constitutive law for concrete, is embedded. In this case, usually quite a few of internal variables, say, the damage variables, are involved, and thus the response processes are not Markovian (Li et al. 2014).

Remark 3 In the GDEE, the randomness involved in the system parameters and external loadings is treated simultaneously in a unified way. Traditionally, in random vibration theory and stochastic structural analysis (stochastic finite element method), the methodologies are quite distinct. But as mentioned before in both branches, huge difficulty is encountered for nonlinear MDOF systems.

Stochastic Harmonic Function Representation of Seismic Ground Motions

Random Function Description of Stochastic Processes

Mathematically, a stochastic process $X(t)$ could be regarded as a family of random variables on a parametric set, say $t \in [0, T]$. For a continuous-parameter process, to characterize the probabilistic information of the stochastic process, the finite-dimensional distributions of PDFs, i.e., $p(x_1, t_1)$, $p(x_1, t_1; x_2, t_2)$, $p(x_1, t_1; x_2, t_2; \dots; x_n, t_n)$, $\dots$, should be specified. By doing so a stochastic process is regarded as a random function of time, but the dependence of X on t is specified not by an explicit expression of t but in an indirect way of specifying the complete cross-probabilistic information of X at all possible different time instants. This description is complete in mathematics. However, two deficiencies exist

for this description at least from the point of view of practical applications (Li et al. 2012b): (i) even if the finite-dimensional distributions are known, how the process X depends on t is still not clear in a sense of physics, but this might be very important for a practical physical problem, and (ii) to capture the high-dimensional distributions of general type other than joint normal distribution by observed information, huge data and prohibitively computational efforts are needed, which is usually impractical either due to lack of data or due to computational difficulty induced by the so-called curse of dimension.

A conceptually more accessible way to a stochastic process is the involvement of an abstract argument representing a sample point, and thus a stochastic process is denoted by $X(\varpi, t)$, where ϖ denotes a sample point in the sample space. By this it is very clear that X is a multi-argument function of ϖ and t . Because X is a function of ϖ , it is “stochastic” in nature. Simultaneously because X is also a function of t , it is a “process.” Thus $X(\varpi, t)$ is a stochastic process. For practical applications the deficiency of this description is that ϖ is a mathematically abstract point in the sample space and its relation to the physical entities is still not exposed. A further step could be made by introducing the embedded basic random variables in the physical problems under consideration, denoted by $\Theta(\varpi) = [\Theta_1(\varpi), \Theta_2(\varpi), \dots, \Theta_s(\varpi)]$ for convenience, and thus a stochastic process could be represented by $X(\varpi, t) = g(\Theta(\varpi), t)$, where $g(\cdot)$ is an explicit function of $\Theta(\varpi)$ and t . The form of $g(\cdot)$ could be determined by the embedded physical mechanism or by mathematical decomposition if phenomenological statistical models are involved, as shown in the following subsections.

Dynamic excitations encountered in engineering, e.g., earthquakes, wind, and waves, are originated with the embedded physical mechanism (Li et al. 2012b, Lin et al. 2012), although the knowledge on these physical phenomena is still at different levels, some even in very preliminary stage. One of the obstacles to understand these phenomena is the large degree of uncertainty involved and exposed as irregularity in the observed data. However, if the embedded

physical mechanism is extracted, then the problem will be understood and captured in a much clearer and easier way. For details, refer to Li et al. (2012b) and Wang and Li (2011).

Representations Based on Mathematical Decomposition

The first two moments, i.e., the mean and the correlation function, could usually capture the major characteristics of a stochastic process. Particularly, these two functions are complete for a Gaussian process. For a zero-mean Gaussian stationary process, the power spectral density function (PSD) is adequate to capture its probabilistic information. These functions essentially belong to phenomenological descriptions although in some cases the physical mechanism is involved when deriving the PSD, e.g., in the Kanai-Tajimi spectrum for ground motions (Tajimi 1960). However, due to its simplicity PSD models are widely employed in most engineering disciplines including earthquake engineering, ocean engineering, wind engineering, etc. Thus, how to represent a stochastic process in time domain by an explicit random function given its PSD is very important. A variety of methods including the Karhunen-Loève decomposition, the spectral representations and improvements were developed (Spanos et al. 2007; Shinozuka and Deodatis 1991; Grigoriu 2002).

The most widely used is the spectral representation method, by which a stochastic process is regarded as the sum of a series of harmonic functions with random phase, i.e.,

$$\hat{X}(t) = \sum_{j=1}^N A_j \cos(\omega_j t + \phi_j) \quad (11)$$

where A_j are deterministic amplitudes; ω_j are deterministic frequencies as inner points, say, uniformly spaced in the interval $[\omega_L, \omega_u]$ over which one-sided PSD is defined; and ϕ_j are independent random variables with identical uniform distribution over $[0, 2\pi]$. Clearly, $\mu_{\hat{X}} = E[\hat{X}(t)] = 0$, and $\sigma_{\hat{X}}^2(t) = E[\hat{X}^2(t)] = \sum_{j=1}^N \frac{A_j^2}{2}$. If the target one-sided

PSD is $G_X(\omega) = 2S_X(\omega)$ for $\omega \geq 0$ and otherwise $G_X(\omega) = 0$, where $S_X(\omega)$ is the double-sided PSD and symmetric to zero, then

$$\sigma_X^2(t) = \frac{1}{2\pi} \int_{\omega_L}^{\omega_u} G_X(\omega) d\omega \approx \sum_{j=1}^N \frac{1}{2\pi} G_X(\omega_j) \Delta\omega_j,$$

where $\Delta\omega_j$ is the length of the j -th frequency subinterval. Letting $\sigma_X^2(t) = \sigma_X^2(t)$ and comparing the terms one to one lead immediately to

$$A_j = \sqrt{\frac{1}{\pi} G_X(\omega_j) \Delta\omega_j} = \sqrt{\frac{2}{\pi} S_X(\omega_j) \Delta\omega_j}.$$

The properties of the representation in Eq. 11 were elaborately studied in Shinozuka and Deodatis (1991). It should be noted that the expression of the amplitude may vary in different literature due to the different position of the factor $\frac{1}{2\pi}$ in the Fourier transform. The spectral representation method is very simple and straightforward, but usually hundreds or even thousands of terms have to be retained. This leads to a large number of random variables, which induces difficulty in practice. To reduce the number of random variables is of great importance (Spanos et al. 2007).

A modification is to randomize the frequencies, and thus Eq. 11 is modified to

$$\tilde{X}(t) = \sum_{j=1}^N A(\tilde{\omega}_j) \cos(\tilde{\omega}_j t + \phi_j) \quad (12)$$

where $\tilde{\omega}_j$ are now random variables. For simplicity, assume the subintervals over which $\tilde{\omega}_j$ distribute are not overlapping, and construct a partition of $[\omega_L, \omega_u]$, i.e., the support of PDF of $\tilde{\omega}_j$ is $[\omega_{j-1}^{(p)}, \omega_j^{(p)}]$, $\omega_0^{(p)} = \omega_L$, $\omega_N^{(p)} = \omega_u$, $\omega_0^{(p)} < \omega_1^{(p)} < \dots < \omega_{N-1}^{(p)} < \omega_N^{(p)}$, and there are $\cup_{j=1}^N [\omega_{j-1}^{(p)}, \omega_j^{(p)}] = [\omega_L, \omega_u]$ and $[\omega_{j-1}^{(p)}, \omega_j^{(p)}] \cap [\omega_{k-1}^{(p)}, \omega_k^{(p)}] = \emptyset$. In this case, there is

$$\sigma_{\tilde{X}}^2(t) = E[\tilde{X}^2(t)] = \sum_{j=1}^N \frac{1}{2} E[A^2(\tilde{\omega}_j)] \quad (13)$$

and $\sigma_X^2(t) = \frac{1}{2\pi} \int_{\omega_L}^{\omega_u} G_X(\omega) d\omega = \sum_{j=1}^N \frac{1}{2\pi} \int_{\omega_{j-1}^{(p)}}^{\omega_j^{(p)}} G_X(\omega) d\omega$. Letting $\sigma_{\tilde{X}}^2(t) = \sigma_X^2(t)$ and

making the terms identical one to one lead to

$$E[A^2(\tilde{\omega}_j)] = \frac{1}{\pi} \int_{\omega_{j-1}^{(p)}}^{\omega_j^{(p)}} G_X(\omega) d\omega. \text{ If the PDF of } \tilde{\omega}_j \text{ is } p_{\tilde{\omega}_j}(\omega), \text{ then it follows that } \int_{\omega_{j-1}^{(p)}}^{\omega_j^{(p)}} A^2(\omega) p_{\tilde{\omega}_j}(\omega) d\omega = \frac{1}{\pi} \int_{\omega_{j-1}^{(p)}}^{\omega_j^{(p)}} G_X(\omega) d\omega, \text{ which leads to}$$

$$A(\tilde{\omega}_j) = \sqrt{\frac{G_X(\tilde{\omega}_j)}{\pi p_{\tilde{\omega}_j}(\tilde{\omega}_j)}} \quad (14)$$

The representation in Eq. 12 is called the stochastic harmonic function representation (SHF) and is of great flexibility by choosing different PDFs for the randomized frequencies (Chen et al. 2013). Particularly, if the PDF of $\tilde{\omega}_j$ takes the shape of PSD, i.e.,

$$p_{\tilde{\omega}_j}(\omega) = G_X(\omega) / \int_{\omega_{j-1}^{(p)}}^{\omega_j^{(p)}} G_X(\omega) d\omega, \text{ then Eq. 14}$$

$$\text{becomes } A(\tilde{\omega}_j) = \sqrt{\frac{1}{\pi} \int_{\omega_{j-1}^{(p)}}^{\omega_j^{(p)}} G_X(\omega) d\omega}. \text{ This is}$$

called the SHF of the first kind (SHF-I). If $\tilde{\omega}_j$ follows the uniform distribution over $[\omega_{j-1}^{(p)}, \omega_j^{(p)}]$, then from Eq. 14 there is $A(\tilde{\omega}_j) = \sqrt{\frac{1}{\pi} G_X(\tilde{\omega}_j) (\omega_j^{(p)} - \omega_{j-1}^{(p)})}$. This is called the SHF of the second kind (SHF-II).

What should be stressed is that the SHF representations are exact in the sense of reproducing the target PSD exactly. This is superior to the spectral representation method which is an approximate approach. Besides, studies show that although any arbitrary number of components could reproduce the target PSD, usually about 7–10 components are adequate considering the shape of the samples and the one-dimensional PDF of the generated process.

Numerical Algorithms

Although for some simple systems the analytical solution of GDEE is possible, for most practical problems, numerical algorithms are needed.

Procedures of Solution

The task is to obtain the instantaneous PDF $p_{Y_\ell}(y, t)$. For this purpose, the GDEE (Eq. 10) should be firstly solved under appropriate initial and boundary conditions which usually take

$$\left. \begin{aligned} p_{Y_\ell \Theta}(y, \theta, t) \Big|_{t=t_0} &= \delta(y - y_{\ell,0}) p_{\Theta}(\theta) \\ p_{Y_\ell \Theta}(y, \theta, t) \Big|_{y \rightarrow \pm\infty} &= 0 \end{aligned} \right\} \quad (15)$$

if the initial value $y_{\ell,0}$ is deterministic and independent of the random parameters. After Eq. 10 is solved Eq. 7 is employed to yield $p_{Y_\ell}(y, t)$. However, to solve the GDEE (Eq. 10), the coefficient $\dot{Y}_\ell(\theta, t)$ should be determined first. This comes from the embedded physical mechanism and is the solution of the physical equation (Eq. 1, or equivalently Eq. 2). Accordingly, the procedure of solution includes the following steps:

Step 1. Specify a representative point set $Q = \{\theta_q = (\theta_{1,q}, \dots, \theta_{s,q}) | \theta_q \in \Omega_\Theta, q = 1, 2, \dots, n_{pt}\}$ and the corresponding assigned probabilities $P_q, q = 1, 2, \dots, n_{pt}$, where n_{pt} is the total number of selected points and $0 < P_q < 1, \sum_{q=1}^{n_{pt}} P_q = 1$. This could be regarded as a first partial discretization of Eq. 10.

Step 2. For each specified $\{\Theta = \theta_q\}$, carry out deterministic analysis, say, the time integration method (Belytschko et al. 2000), to solve the physical equation (Eq. 1, or Eq. 2) to yield $\dot{Y}_\ell(\theta_q, t)$.

Step 3. Substitute $\dot{Y}_\ell(\theta_q, t)$ in the GDEE (Eq. 10) and solve it under the boundary and initial conditions (Eq. 15) by, say, the finite difference method with TVD scheme to yield the numerical result of $p_{Y_\ell \Theta}(y, \theta_q, t)$.

Step 4. Make a summation according to Eq. 7 to yield the numerical results of the instantaneous PDF $p_{Y_\ell}(y, t)$, i.e., $p_{Y_\ell}(y, t) = \sum_{q=1}^{n_{pt}} p_{Y_\ell \Theta}(y, \theta_q, t)$.

Optimal Selection of Representative Points

The point selection in Step 1 is of paramount importance to the efficiency and accuracy of PDEM. A consistent treatment is based on the partition of probability assigned space (Li et al. 2012a).

Let Ω_q denote the representative space of the point θ_q . Ω_q s construct a partition of Ω_Θ , i.e., $\bigcup_{q=1}^{n_{pt}} \Omega_q = \Omega_\Theta$ and $\Pr\{\omega \in \Omega_q \cap \Omega_k\} = 0$ for any $q \neq k$, where $\Pr\{\cdot\}$ denotes the probability of the event. The assigned probability of the point θ_q is then specified by $P_q = \int_{\Omega_q} p_\Theta(\theta) d\theta$, which clearly satisfies $0 < P_q < 1$ and $\sum_{q=1}^{n_{pt}} P_q = 1$. For problems with $2 \leq s \leq 4$, the method based on tangent spheres performs well, while for problems with $2 \leq s \leq 18$, the number theoretical method together with hyper-ball sieving could be employed (Li and Chen 2009). A versatile approach based on the generalized F-discrepancy (GF-discrepancy) was recently developed for general nonuniform, non-normal distributions.

Let the marginal cumulative distribution function (CDF) of the basic random variable Θ_j , $j = 1, 2, \dots, s$ be $F_j(\theta) = \int_{-\infty}^{\theta} p_{\Theta_j}(x) dx$. Denote the empirical marginal CDF of Θ_j by $\tilde{F}_j(\theta; Q) = \sum_{q=1}^{n_{pt}} P_q I\{\theta_{j,q} < \theta\}$, where $I\{\cdot\}$ is the indicator function of which the value is 1 when the bracketed event is true, and otherwise zero, $\theta_{j,q}$ is the j -th component of θ_q . By these a GF-discrepancy could be introduced:

$$D_{GF}(Q) = \max_{1 \leq j \leq s} \left\{ \sup_{-\infty \leq \theta \leq \infty} |\tilde{F}_j(\theta; Q) - F_j(\theta)| \right\} \quad (16)$$

It is demonstrated that the smaller the GF-discrepancy, the better the performance of the point set in the sense that the error of the involved high-dimensional integral is smaller (Chen and Zhang 2013). Therefore, the task is now to find some point set Q minimizing the GF-discrepancy, i.e.,

$$\begin{aligned} Q &= \arg[\min D_{GF}(Q)] \\ &= \arg \left[\min \left(\max_{1 \leq j \leq s} \left\{ \sup_{-\infty \leq \theta \leq \infty} |\tilde{F}_j(\theta; Q) - F_j(\theta)| \right\} \right) \right] \end{aligned} \quad (17)$$

Plenty of optimization methods could be adopted to complete this task and yield the optimal representative point set.

Finite Difference Method with TVD Scheme

In Step 3 a series of partial differential equations are solved. These equations are of the form

$$\frac{\partial p(y, t)}{\partial t} + a \frac{\partial p(y, t)}{\partial y} = 0 \quad (18)$$

for different values of a in the case of different θ_q . Quite a few difference schemes were developed. According to computational experiences the schemes with TVD (total variation diminishing) property are satisfactory (Li and Chen 2009). One of such schemes that is adopted is as follows:

$$\begin{aligned} p_j^{(k+1)} &= p_j^{(k)} - \frac{1}{2}(\lambda a - |\lambda a|) \Delta p_{j+\frac{1}{2}}^{(k)} - \frac{1}{2}(\lambda a + |\lambda a|) \Delta p_{j-\frac{1}{2}}^{(k)} \\ &\quad - \frac{1}{2}(|\lambda a| - |\lambda a|^2) (\psi_{j+\frac{1}{2}} \Delta p_{j+\frac{1}{2}}^{(k)} - \psi_{j-\frac{1}{2}} \Delta p_{j-\frac{1}{2}}^{(k)}) \end{aligned} \quad (19)$$

where $p_j^{(k)}$ denotes $p(x_j, t_k)$, $x_j = j\Delta x$, $j = 0, \pm 1, \pm 2, \dots$, $t_k = k\Delta t$, $k = 0, 1, 2, \dots$, and Δx and Δt are the space and time step, respectively; the mesh ratio $\lambda = \Delta t/\Delta x$; $\Delta p_{j+\frac{1}{2}}^{(k)} = p_{j+1}^{(k)} - p_j^{(k)}$; and $\Delta p_{j-\frac{1}{2}}^{(k)} = p_j^{(k)} - p_{j-1}^{(k)}$. The factors $\psi_{j+\frac{1}{2}}, \psi_{j-\frac{1}{2}}$ are called the flux limiters, which are related to the irregularity of the curve of $p(x, t)$ in terms of x . As $\psi_{j+\frac{1}{2}} = \psi_{j-\frac{1}{2}} \equiv 1$ the scheme in Eq. 19 reduces to the well-known Lax-Wendroff scheme, whereas as $\psi_{j+\frac{1}{2}} = \psi_{j-\frac{1}{2}} \equiv 0$ the scheme in Eq. 19 reduces to the one-sided scheme. To achieve the TVD property, $\psi_{j+\frac{1}{2}}, \psi_{j-\frac{1}{2}}$ should depend on the parameters characterizing the irregularity of $p(x, t)$, i.e.,

$$\begin{aligned} r_{j+\frac{1}{2}}^+ &= \frac{\Delta p_{j+\frac{3}{2}}^{(k)}}{\Delta p_{j+\frac{1}{2}}^{(k)}} = \frac{p_{j+2}^{(k)} - p_{j+1}^{(k)}}{p_{j+1}^{(k)} - p_j^{(k)}}, \\ r_{j+\frac{1}{2}}^- &= \frac{\Delta p_{j-\frac{1}{2}}^{(k)}}{\Delta p_{j+\frac{1}{2}}^{(k)}} = \frac{p_j^{(k)} - p_{j-1}^{(k)}}{p_{j+1}^{(k)} - p_j^{(k)}} \end{aligned} \quad (20)$$

The flux limiter $\psi_0(r) = \max(0, \min(2r, 1), \min(r, 2))$ could be recommended and then

$$\psi_{j+\frac{1}{2}}\left(r_{j+\frac{1}{2}}^+, r_{j+\frac{1}{2}}^-\right) = u(-a)\psi_0\left(r_{j+\frac{1}{2}}^+\right) + u(a)\psi_0\left(r_{j+\frac{1}{2}}^-\right) \quad (21)$$

where $u(\cdot)$ is Heaviside's function, of which the value is 1 if the argument is greater than 0 and is zero otherwise.

First-Passage Reliability and Global Reliability

First-Passage Reliability

The first-passage reliability is of great concern to engineering structures exposed to disastrous dynamic excitations. For instance, if the first-passage failure is defined in terms of $Y_\ell(t)$, the reliability is then

$$R(t) = \Pr\{Y_\ell(\Theta, \tau) \in \Omega_s, \text{ for } 0 \leq \tau \leq t\} \quad (22)$$

Note that the evolution of the probability density of $(Y_\ell(t), \Theta)$ is governed by Eq. 10. Eq. 22 means that once the probability outcrosses the boundary of the safety domain, then it will not return to the safety domain. This could be expressed mathematically as an absorbing boundary condition

$$p_{Y_\ell, \Theta}(y, \theta, t)|_{y \in \Omega_f} = 0 \quad (23)$$

where Ω_f is the failure domain. This of course is also equivalent to imposing the absorbing boundary condition $p_{Y_\ell}(y, t)|_{y \in \Omega_f} = 0$ for Eq. 5. Replacing the boundary condition in Eq. 15 by Eq. 23 and carrying out the procedures in the preceding section will yield the "remaining" PDF $\tilde{p}_{Y_\ell}(y, t)$, and thus the reliability is given by

$$R(t) = \int_{\Omega_s} \tilde{p}_{Y_\ell}(y, t) dy = \int_{-\infty}^{\infty} \tilde{p}_{Y_\ell}(y, t) dy \quad (24)$$

Global Reliability

Traditionally, it is called the system reliability if more than one failure modes are involved.

However, due to the fact that the failure of a global structure is usually dependent on the whole process of development of nonlinearity in the system, the reliability should be captured in this whole process involving randomness. In this sense, it is more appropriate to call it the global reliability of a structure (Chen and Li 2007; Li and Chen 2009). For instance, if the failure of the global structure is determined by some combinations or even functional of $Y_\ell(\Theta, t)$ and $Y_k(\Theta, t)$, say, the Park-Ang model (Park and Ang 1985), then a corresponding equivalent process, denoted as $Z(t) = f[Y_k(\Theta, \tau), Y_\ell(\Theta, \tau); 0 \leq \tau \leq t]$ for convenience, as some kind of compound or even functional of $Y_\ell(\Theta, t)$ and $Y_k(\Theta, t)$, could be constructed such that the global reliability is given by $R_G(t) = \Pr\{Z(\Theta, \tau) \in \Omega_s, \text{ for } 0 \leq \tau \leq t\}$. Then the method similar to that described in the above subsection could be adopted, or the PDF of the equivalent extreme value $\max_{0 \leq \tau \leq t} Z(\Theta, \tau)$ could be obtained, and then the global reliability is yielded (Li et al. 2007, Li & Chen 2009).

Numerical Example of Applications

To illustrate the PDEM, a 10-story floor-shear structure with lumped masses on the floors subjected to stochastic ground motion is studied. To be simple, all the system parameters are taken as deterministic variables. The lumped masses from bottom to top are 1.5, 1.5, 1.5, 1.4, 1.4, 1.4, 1.3, 1.3, 1.3, and $0.7 (\times 10^5 \text{ kg})$, respectively; the inter-story stiffness from bottom to top are 4.25, 4.25, 4.25, 4.25, 4.0, 4.0, 4.0, 4.0, 3.5, and $3.5 (\times 10^{10} \text{ N/m})$. Rayleigh damping is adopted, i.e., the damping matrix $\mathbf{C} = a\mathbf{M} + b\mathbf{K}$, where $\mathbf{M}$ and $\mathbf{K}$ are the mass and stiffness matrix, and $a = 0.01$ and $b = 0.005$. The Bouc-Wen model is taken to characterize the hysteretic behavior of the restoring force (Ma et al. 2004; Li and Chen 2009), where the basic parameters take $A = 1$, $n = 1$, $q = 0$, $p = 600$, $d_\psi = 0$, $\lambda = 0.5$, $\psi = 0.2$, $\beta = 60$, $\gamma = 10$, $d_v = 200$, $d_\eta = 200$, and $\zeta = 0.95$. For the linear system $\alpha = 1$, and for the nonlinear system $\alpha = 0.01$.

**Probability Density
Evolution Method in
Stochastic Dynamics,
Fig. 1 Target and
reproduced PSD**

The Kanai-Tajimi spectrum is taken as the target spectrum of the stochastic ground motions, i.e.,

$$S(\omega) = \frac{1 + 4\zeta_0^2(\omega/\omega_0)^2}{(1 - (\omega/\omega_0))^2 + 4\zeta_0^2(\omega/\omega_0)^2} S_0 \quad (25)$$

where $S(\omega)$ is the PSD, $\omega_0 = 16.9$, $\zeta_0 = 0.94$, and $\omega_u = 100$ rad/s. S_0 is such determined that the standard deviation of the ground motion acceleration is 1.0 m/s^2 .

In Fig. 1 shown is the target PSD in Eq. 25 (labeled as “K-T spectrum”) and the PSD reproduced by the SHF-II including 20 terms. It is seen that with only 20 SHF components, the PSD could be reproduced in high accuracy. This will also result with high accuracy in the second-order statistics of response of the linear system, but for the nonlinear structure, it seems that more terms should be retained. Figure 2 shows typical curves of restoring force vs. inter-story drift, demonstrating that in the nonlinear case strong hysteresis is involved. In Fig. 3 pictured are the mean and standard deviation of response (top displacement) of linear and nonlinear structures by PDEM and 20,000 times of Monte Carlo simulations (labeled as “MCS”), respectively. In this paper 800 representative time histories generated by SHF-II are adopted. Computational

experiences show that this number could still be reduced. Theoretically, the mean of linear and nonlinear structures should be zero due to the symmetry of distribution of the input ground acceleration process. This is clearly verified from the upper figure of Fig. 3, which shows that the mean by the PDEM is quite small in comparison to the standard deviation (the coordinate in the upper figure of Fig. 3 is in the order of magnitude of the standard deviation). Also it is seen that the standard deviation of the nonlinear response is smaller than that of the linear structure. Pictured in Fig. 4 are the PDF evolution surfaces during an identical period for linear and nonlinear systems. Note that if the input is Gaussian, the output should also be Gaussian for linear systems. Clear differences between the PDFs of linear and nonlinear responses could be observed from the figures.

It is noted that by PDEM the global reliability of the structure could also be obtained by imposing absorbing conditions. In Fig. 5 shown are the time-variant first-passage reliabilities of the nonlinear structure in ordinary and logarithmic coordinates for different threshold values by PDEM and Monte Carlo simulation (20,000 times). The thresholds 0.4, 0.3, 0.25, and 0.2 m correspond to the displacement angle of $1/75$, $1/100$, $1/120$, and

Probability Density Evolution Method in Stochastic Dynamics, Fig. 2 Typical restoring force

Probability Density Evolution Method in Stochastic Dynamics, Fig. 3 The mean and standard deviation

1/150, respectively. It is shown that the reliability decreases almost continuously from some time monotonically, but noticeably not in an exponential way as predicted by the Poisson assumption. Actually, from Fig. 5b it

is seen that the absolute value of slope of the logarithmic reliability is increasing, which means that the hazard rate of the structure exhibiting nonlinear behaviors is increasing as the time elapses.

Summary

The probability density evolution method is outlined and illustrated in this entry. It is concluded that (1) the thought of physical stochastic systems provides a new perspective to stochastic dynamics and (2) the probability density evolution method shows its versatility in stochastic dynamics, particularly for MDOF nonlinear systems subjected to non-white noise excitations. However, improvements and extension of the physical stochastic models of dynamic excitations and more robust and efficient numerical algorithms are still needed.

Introduction

Studies on seismic hazard mitigation are important for seismologists, earthquake engineers, and

related scientists. Among studies, probabilistic seismic hazard assessments (PSHAs) provide the probability of exceedance for a specific ground motion level during a time interval (see entry “► [Site Response for Seismic Hazard Assessment](#)”). PSHA results can provide a key reference for the determination of hazard mitigation policies related to building codes and the site selection of public structures. Therefore, multidisciplinary scientists have attempted to build reliable systems for PSHAs.

Due to the plate boundary between the Eurasian and Philippine Sea Plates, Taiwan has a high earthquake activity (Fig. 1). In this region, devastating earthquakes lead to a loss of property and human life. Therefore, it is essential to develop a means of seismic hazard mitigation. One practical approach is to build a seismic hazard assessment system. Over the past few years, several studies have evaluated seismic hazards for Taiwan. For example, the Global Seismic Hazard Assessment Program (GSHAP, <http://www.seismo.ethz.ch/static/GSHAP/>) obtained a global probabilistic seismic hazard map that included Taiwan. However, this work employed earthquake catalogs obtained from global seismic networks rather than a detailed seismicity catalog from Taiwan. Another application was proposed by Campbell et al. (2002) who utilized seismic catalogs, active fault parameters, and ground motion prediction equations (GMPEs) for the world, the United States, and Taiwan. Cheng et al. (2007) evaluated seismic hazards for Taiwan and proposed a hazard map by integrating a catalog from a local network, active fault parameters, and seismogenic zones in Taiwan. Such studies are crucial for understanding seismic hazards in Taiwan. However, following these studies, many parameters and the database for seismic hazard assessments, such as understanding the tectonic setting, the distribution of active faults, GMPEs, and earthquake catalogs, have been revised and/or updated. By employing state-of-the-art parameters, an evaluation of seismic hazards can be more precise.

Seismic hazards for Taiwan are reevaluated through the PSHA approach as proposed by

Cornell (1968). According to this approach, parameters for seismogenic sources, which may result in seismic hazards, are required. Several seismogenic sources were characterized, including shallow regional sources, deep regional sources, crustal active fault sources, subduction intraslab sources, and subduction interface sources. The parameters for each source are discussed according to information from the tectonic setting, geology, geomorphology, geophysics, and earthquake catalog and present the results in the form of hazard maps and hazard curves. The results are compared with those proposed by previous studies and discuss their applicability for the future.

Methodologies and Seismic Activity Models

The PSHA Approach

The applied approach of PSHA was first developed by Cornell (1968) (see entry “Earthquakes and Tectonics: Probabilistic Seismic Hazard Assessment: An Overview”). According to the description of Kramer (1996), seismic hazards based on this approach can be assessed, as follows:

$$P[Y > y^*] = \iint P[Y > y^* | m, r] f_M(m) f_R(r) dm dr, \quad (1)$$

where $P[Y > y^*]$ is the probability, P , for a given ground motion parameter, Y , which exceeds a specific value, y^* . $P[Y > y^* | m, r]$ is the probability conditional on an earthquake with magnitude, m , imparted by a seismogenic source with the closest distance, r , between the site of interest and seismogenic source; and $f_M(m)$ and $f_R(r)$ are the probability density functions for magnitude and distance, respectively.

If there are N_S potential seismogenic sources near the site of interest, each of which has an average rate, ν_i . The total average exceedance rate, $\lambda_{y^*,0}$, for the region can be presented as follows:

$$\lambda_{y^0} = \sum_{i=1}^{N_S} v_i \iint P[Y > y^* | m, r] f_{M_i}(m) f_{R_i}(r) dm dr, \quad (2)$$

where $\sum_{n=1}^{N_S}$ is the summation of the contribution from N_S th seismogenic sources n .

PSHA uncertainties from different aspects were considered and properly treated. A logic tree approach was introduced to incorporate the uncertainties for seismogenic sources, the corresponding parameters of each source, and the GMPEs. The treatment of the weighting for each parameter is discussed in subsequent sections.

Seismic Activity Models

For the implementation of PSHA, the corresponding seismicity rate as a function of magnitude for each seismogenic source should be introduced (Eq. 2). Generally, there are two

models that present the relationships, the truncated exponential model and the characteristic earthquake model. In the following, both of these models are presented and discussed.

The Truncated Exponential Model

The truncated exponential model is based on Gutenberg-Richter's Law (G-R Law) (Gutenberg and Richter 1954), as follows:

$$\log(\dot{N}) = a - bM \quad (3)$$

where $\dot{N}$ is the annual rate for events with magnitudes larger than or equal to M and a and b are constants with values larger than 0. Following on G-R Law, the truncated exponential model represents the rate for a magnitude larger than the maximum magnitude, m_u , as 0. Thus, the cumulative annual rate, $\dot{N}(m)$, for a magnitude larger than or equal to m can be presented, as follows:

$$\dot{N}(m) = \dot{N}(m_0) \frac{\exp(-\beta(m - m_0)) - \exp(-\beta(m_u - m_0))}{1.0 - \exp(-\beta(m_u - m_0))} \quad \text{for } m_u \geq m \geq m_0 \quad (4)$$

where $\dot{N}(m_0)$ represents the cumulative annual rate for a magnitude of a minimum magnitude, m_0 , and m_0 and m_u represent the minimum and maximum magnitudes, respectively, of the seismogenic source. β can be represented as follows:

$$\beta = b \cdot \ln(10) \quad (5)$$

where b is the b -value in G-R Law (Eq. 3).

Wesnousky (1994) concluded that this model is suitable for regions with complex tectonic settings or multiple active faults. Thus, it was applied

for shallow regional sources, deep regional sources, and subduction intraslab sources.

The Characteristic Earthquake Model

The characteristic earthquake model was first proposed by Youngs and Coppersmith (1985). In addition to earthquake parameters, the model represents the seismicity rate by incorporating geological and geomorphological information. The cumulative annual rate for a magnitude larger or equal to m can be represented as follows:

$$\begin{aligned} \dot{N}(m) &= \dot{N}^e \frac{\exp(-\beta(m - m_0)) - \exp(-\beta(m_u - 1/2 - m_0))}{1.0 - \exp(-\beta(m_u - 1/2 - m_0))} + \dot{N}^c \quad \text{for } m_0 \leq m \\ &\leq m_u - \frac{1}{2}; \quad \dot{N}(m) = \dot{N}^c \frac{m_u - m}{1/2} \quad \text{for } m_u - \frac{1}{2} \leq m \leq m_u, \end{aligned} \quad (6)$$

where $\dot{N}^e$ and $\dot{N}^c$ represent the cumulative annual rates predicted by the truncated exponential and

the characteristic earthquake models, respectively. $\dot{N}^e$ can be presented, as follows:

$$\dot{N}^e = \frac{\mu A_f S \cdot (1 - \exp(-\beta(m_u - m_0 - 1/2)))}{\exp(-\beta(m_u - m_0 - 1/2)) \cdot M_0(m_u) \cdot \left[\frac{b \cdot 10^{-c/2}}{(c-b)} + \frac{b \exp(\beta)(1 - 10^{-c/2})}{c} \right]}, \quad (7)$$

where μ is the rigidity shear modulus, generally assumed to be 3×10^{10} Pascal (N/m²); A_f is the fault area; S is the slip rate; and c and d are constants. $\dot{N}^c$ can be represented as follows:

$$\dot{N}^c = \frac{1}{2} \dot{N}^e \frac{b \ln 10 \cdot \exp(-\beta(m_u - 3/2 - m_0))}{(1 - \exp(m_u - 1/2 - m_0))}. \quad (8)$$

In a comparison with the truncated exponential model, the characteristic earthquake model predicted lower rates for smaller magnitudes, whereas higher rates were predicted for larger magnitudes (Youngs and Coppersmith 1985).

To implement the characteristic earthquake model for PSHA, the cumulative annual rate should be in form of the rate $\lambda_n(m_i)$ (Eq. 2) between the magnitude bins of $m_i \pm dm/2$, which can be represented as follows:

$$\lambda_n(m_i) = N(m_i - dm/2) - N(m_i + dm/2), \quad (9)$$

where dm is the magnitude interval for the model and $N(m_i)$ is the rate for a magnitude larger or equal to m_i .

A few previous studies (Youngs and Coppersmith 1985; Wesnousky 1994) have suggested that the behavior of seismic activity along crustal active faults and subduction interfaces follows this model. Therefore, it was applied to the two seismogenic sources.

Seismogenic Tectonics in Taiwan

Tectonic Setting

Taiwan is located within the plate boundary between the Philippine Sea Plate and the Eurasian Plate (Fig. 1). Due to the interaction of the two plates, both subduction and collision take place in this region. Two subduction systems

surround this region. In the offshore of northeast Taiwan, the Philippine Sea Plate subducts to the north. As a result of back-arc spreading, the Okinawa Trough and the Ilan Plain formed in the northern section of the Ryukyu Volcanic Arc. In southern Taiwan, the Eurasian Plate subducts to the east. The Longitudinal Valley is the arc-continental collision boundary between the two plates. Collision began in the late Miocene in northern Taiwan. Due to lateral collision between plates, collision activity continues to migrate to the south. Currently, activity takes place in central and southwestern Taiwan. Northern Taiwan, in contrast, is a post-collision region with relatively low seismic activity.

The Earthquake Catalog

The utilized earthquake catalog was collected by the Central Weather Bureau (CWB) and provided earthquake parameters for events from 1900 to 2010 in Taiwan. Prior to 1973, a total of 15 stations equipped with Gray-Milne, Wiechert, or Omori seismographs were maintained. After 1973, the Taiwan Telemetric Seismic Network (TTSN) was established. The TTSN consists of 25 stations within the region of Taiwan. In the TTSN network, real-time signals are transmitted from field stations to a central station via leased telephone lines.

To assess seismic hazards, earthquake parameters should be analyzed using the following procedures: a magnitude harmonization from different scales, an evaluation of the magnitude of completeness, and a declustering process. In the following, each step of the procedure is described in detail.

Magnitude Harmonization

Since the magnitude scales for a catalog during different periods are generally different, it is critical to harmonize the magnitude scales during

Probability Seismic Hazard Mapping of Taiwan, Fig. 1

The tectonic setting in Taiwan and its vicinity (Modified from Cheng et al. 2007)

P

different periods. Previous studies (Hanks and Kanamori 1979 and references therein) have suggested a moment magnitude (M_W) for PSHA, since this scale is evaluated based on rupture dimensions and slip magnitudes. Additionally, the M_W scale is not affected by saturation at higher magnitudes. For example, the 1999 Chi-Chi, Taiwan, earthquake was determined to have a M_W of 7.6, whereas its corresponding M_L was 7.3. The discrepancy can be attributed to the saturation of M_L (Cheng et al. 2007). Therefore, the earthquake catalog obtained by Tsai et al. (2000) was considered. The magnitude scales of this catalog have been harmonized as M_W from 1900 to 1999. The magnitude scales of the catalog were harmonized according to the procedure of Tsai et al. (2000).

Magnitude of Completeness

To improve the reliability of the parameters for seismogenic sources, the catalog during the period when the network recorded all earthquakes with a certain magnitude threshold was considered. The threshold is known as the magnitude completeness, M_c . Thus, M_c for catalogs during different periods must be examined in advance. Chen et al. (2012) evaluated the M_c of the CWB catalog using the maximum curvature method. A higher M_c between 4.3 and 4.8 was obtained prior to 1973. Once the TTSN was established, M_c decreased to between 2.0 and 3.0. Based on the temporal distribution of M_c , $M \geq 6.0$ earthquakes after 1900 (Fig. 2) and $M \geq 2.0$ earthquakes after 1973 (Fig. 3) were considered.

Probability Seismic Hazard Mapping of Taiwan, Fig. 2 The distribution of earthquakes with $M \geq 6.0$ at the depth of (a) ≤ 35 km and (b) > 35 km since 1900. The distribution of shallow and deep regional sources is

illustrated by the *blue polygons* in Fig. 2a and b, respectively. In Fig. 2a, crustal active fault sources are presented as *red lines*

The Declustering Process

For application of the PSHA approach by Cornell (1968), it is assumed that the occurrence of earthquakes follows the Poisson procedure. In other words, earthquakes are independent of one another. However, in a catalog, earthquake sequences, which include foreshocks, mainshock, aftershocks, and swarms, can be observed. Therefore, it is critical to obtain a declustered catalog in respect to the PSHA (i.e., to remove foreshocks, aftershocks, and swarms from the catalog). The declustering approaches developed by Wyss (1979), Arabasz and Robinson (1976), Gardner and Knopoff (1974), and Uhrhammer (1986) were implemented. According to these approaches, earthquakes are considered dependent when their distance and

time are within the windows (Fig. 4). Earthquakes are regarded as foreshocks or aftershocks if they fulfill at least two of the four declustering approaches.

Focal Mechanisms

Based on the spatial distribution of the focal mechanisms, the seismogenic region for the PSHA can be distinguished. According to the focal mechanisms determined by Wu et al. (2010), the spatial distribution of the crustal stress state in Taiwan can be illustrated. In northern Taiwan, along the Central Range and in the Okinawa Trough, the stress states are normal favorable. In central Taiwan, southwestern Taiwan, and within the interfaces of subduction systems, the stress states are

Probability Seismic Hazard Mapping of Taiwan, Fig. 3 The distribution of earthquakes with $M \geq 2.0$ at a depth of (a) ≤ 35 km and (b) > 35 km since 1973. In the column of rake, N normal, RL right-lateral, LL left-lateral, T thrust

Probability Seismic Hazard Mapping of Taiwan, Fig. 4 The (a) distance and (b) time windows for each declustering approach. Earthquakes were considered dependent when their distance and time were within the windows

thrust favorable. In northwestern Taiwan, south Taiwan, and along the Longitudinal Valley, the stresses are strike-slip favorable. Additionally, the stress state within the two subduction systems can be comprehended using focal mechanisms determined by Wu et al. (2010).

The distribution of focal mechanisms can be associated with the tectonic setting, as mentioned above (in section “[Tectonic Setting](#)”). Representing the spatial distribution of stress states in each region would be of benefit for the PSHA in respect to the determination of seismogenic sources.

Seismogenic Sources

For application of the PSHA approach of Cornell (1968) (Eq. 2), seismogenic sources and corresponding parameters should be defined. Based on the understanding of each source, three types, Type I, Type II, and Type III (Kiureghian and Ang 1977), can be categorized. Type I is a source with a clear fault geometry, Type II is a source with a clear focal mechanism, and Type III is a source with a controversial fault geometry and mechanism. Type II sources were assumed as “regional sources.” By further considering the depth boundary of 35 km, a “shallow regional source” and a “deep regional source” were defined. Type I sources were treated as “crustal active fault sources” according to the distribution of active faults obtained by the Central Geological Survey (2010, http://fault.moeacgs.gov.tw/TaiwanFaults_2009/News/NewsView.aspx?id=3). Since two subduction systems exist in Taiwan (Fig. 1) and since the ground motion attenuation behaviors of intraslab and interface events are different, “subduction intraslab sources” and “subduction interface sources” were considered. In the following, each seismogenic source and the corresponding parameters are described in detail. For application of the logic tree in the PSHA, the weights for the parameters of each source are also required. In the following, the treatment of the weighting is described in detail.

Shallow Regional Sources

Using information on geomorphology, seismology, and geophysics, 28 shallow regional sources were defined in Taiwan and its vicinity (Fig. 5). The geometry and the corresponding parameters of each zone are outlined in the following sections.

The Geometry of Each Source

S01, S02, and S03 are located in the stable Eurasian Continental Plate. In these sources, seismicity rates are relatively low in comparison to the region surrounding Taiwan Island. The boundary between S01 and S02 was determined based on the extended alignment of the structure in Taiwan. Additionally, earthquakes for the two sources present different focal mechanisms (Wu et al. 2010). The southern boundary of S02 is defined by the accretionary wedge of the southern subduction zone system. The eastern boundary of S03 is defined by the southern subduction zone system (Fig. 1).

At S04, the focal mechanisms suggest normal favorability, which is significantly different from that in its vicinity (Wu et al. 2010). S05A displays a transient mechanism from the normal mechanism in the northeast (S04) to the strike-slip and one located in the southwest (S05B). The eastern boundary of the two sources is defined based on different mechanisms from S09, where the dipping angles of earthquakes are close to vertical and mechanisms are normal favorable. S06 belongs to the frontal deformation region in the Western Foothills. Both the southern and northern boundaries are defined by fault segmentations and changes in the fault alignments (Fig. 2a). The western boundary is marked by the boarder of the Peikang High (Fig. 1). The eastern boundary is defined due to different mechanisms from S10, where the dipping angles are close to vertical and earthquakes are the normal favorable mechanism.

S07 is also located in the frontal deformation region within the Western Foothills. The eastern boundary is defined according to a significantly different seismicity rate from S11. S08A and S08B are located in the transition region between the frontal deformation region on the north and the subduction system on the south. In comparison with the thrust mechanisms in S07, earthquakes within S08A are strike-slip types with a

Probability Seismic Hazard Mapping of Taiwan, Fig. 5 The distribution of shallow regional sources

thrust component. The eastern boundary with S12 was determined according to heterogeneous deformation behaviors obtained from GPS observations (Hsu et al. 2009).

S09, S10, S11, and S12 are located within the transition region from the frontal deformation region in the west to the collision boundary between the Eurasian and Philippine Sea Plates in the east. The principal stress axis is vertical. The four sources are distinguished by strike orientations (from a NE-SW orientation in the north to a N-S orientation in the south) and seismicity rates. S13's source is located within the western

flank of the Okinawa Trough. Due to back-arc spreading, the mechanism of earthquakes in this source suggests normal favorability. S14A, S14B, and S14C result from back-arc spreading and subduction. In the three sources, the seismicity rates are high and the seismicity behaviors are complex. The southern boundary is defined according to the interface of the subduction system. The three sources are distinguished by their seismicity rates and mechanisms. S15 and S16 are located in the area where the Philippine Sea Plate subducts to the Eurasian Plate. In general, earthquakes have thrust mechanisms with low

dipping angles. In comparison, the mechanisms in S15 are complex due to the coexistence of plate collision and subduction. For the same reason, the seismicity rate in S15 is higher than that in S16.

S17A, S17B, S18A, and S18B reside along the eastern coastline and in the offshore region, which is in the collision zone between the two plates. The boundary between S17 and S18 is defined by heterogeneities in respect to active fault activity and deformation behavior according to GPS observations (Hsu et al. 2009). Additionally, seismicity rates in S17A and S18A to the west are higher than those in S17B and S18B to the east. Earthquakes in these sources are mainly thrusts with a strike-slip mechanism with high dipping angles.

S19A and S19B include Green Island and Orchid Island and their vicinity. Since 1900, eight earthquakes with $M \geq 6.0$ have taken place in these sources (Fig. 2a). The two sources are distinguished based on differences in the seismicity rate (Fig. 3a). S20 represents the southern offshore region of Taiwan. Additionally, it is above the subduction zone. S21 is located within the Philippine Sea Plate. Since it is located at a distance from the collision zone, the seismicity rate is relatively low (Fig. 1).

The Parameters of Each Source

In the above discussion, the distributions of shallow regional sources were determined. For application of the PSHA, parameters for each source were required. In the following, the acquirement of parameters including the seismicity rate models, maximum magnitudes, and their corresponding weights is described.

Due to insufficient information on fault geometry and the slip rate for regional sources, a truncated exponential model (Eq. 4) is applied for shallow regional sources. The model for each source was obtained through a regression of the declustered catalog using maximum likelihood estimates. For the regression, the magnitude interval for the model (dm in Eq. 7) was assumed to be 0.5. Therefore, the cumulative annual rate ($\dot{N}(m_0)$) and the b -value, as well as the corresponding deviations for each source, were obtained (Table 1).

Another key parameter for the PSHA was the maximum magnitude, m_u . For sources with active faults or subduction systems (i.e., S04, S05A, S05B, S06, S07, S08A, S11, S12, S15, S16, S17A, and S18A) (Fig. 2a), the corresponding m_u 's were generally obtained based on the maximum magnitude of active faults within the source (see section "Crustal Active Fault Sources"). Note that a maximum threshold of 6.5 in these sources was assumed since the occurrence of $M > 6.5$ earthquakes can be attributed to crustal active faults or subduction sources. However, m_u for some sources, S05A, S12, S15, and S16, was determined using other considerations. In S05A, since no earthquake with $M \geq 5.0$ has ever been recorded, a smaller m_u of 5.5 was assumed. In S12, S15, and S16, due to the existence of a subduction interface and other offshore active faults, a larger m_u of 7.0 was assumed. On the other hand, for sources without active faults (i.e., S01, S02, S03, S08B, S09, S10, S13, S14A, S14B, S14C, S17B, S18B, S19A, S19B, S20, and S21), the m_u 's were assumed based on the maximum observed earthquake plus 0.2 for each source (Table 1).

Deep Regional Sources

According to the distribution of seismicity and the tectonic setting, seven deep regional sources were defined in Taiwan and its vicinity (Fig. 6). Note that subduction interfaces were not included with respect to differences in ground motion attenuation behaviors (Lin and Lee 2008). The geometry and the corresponding parameters of each source are discussed in the following sections.

The Geometry of Each Source

Deep regional sources can be separated into two parts. To the east of longitude 121.5°, they are located within the subduction zone in northeast Taiwan. To the south of latitude 23°, they are regarded as another subduction zone in southern Taiwan. D01, D02, and D03 are located within the Eurasian Plate. The boundary between D02 and D03 is located along the latitude of 23°, which is regarded as the border of the continent to the north and the subduction zone to the south. The accretionary wedge of the southern

subduction zone system defines the western boundary of D03. The eastern boundary of D03 is illustrated by the distribution of the southern subduction zone system. To the east of Taiwan, four deep regional sources, including D04, D05, D06, and D07, were identified. Due to plate collision, higher seismicity rates were observed in D04 and D06 (Fig. 3b). In contrast, since it is a part of the deeper part of the Philippine Sea Plate, D07 has a lower seismicity rate. D05 is located within the region where the Philippine Sea Plate subducts to the Eurasian Plate.

The Parameters of Each Source

As a follow-up to the procedure for shallow regional sources, the acquirement of the

corresponding parameters for each deep regional source is described in the following. A truncated exponential model is used to present seismic activity. The cumulative annual rate and the b -value, as well as the corresponding deviations for each source, were obtained (Table 2). The maximum magnitude, m_u , for each source was assumed. Since D01, D02, and D03 are located within the stable Eurasian Continental Plate, a small m_u was assumed. For application of the logic tree, weights of 0.2, 0.6, and 0.2 were assumed for m_u 's of 6.5, 6.6, and 6.7, respectively. Due to the plate collision zone, higher m_u 's of 7.0, 7.2, and 7.4 were assumed for D04. Since earthquakes with $M \geq 6.7$ have never been recorded in D05, D06, and D07, m_u 's of 6.8, 7.0, and 7.2 were assumed.

Probability Seismic Hazard Mapping of Taiwan, Fig. 7 The distribution of shallow regional (blue polygons) and crustal active fault sources (red lines). The corresponding shallow regional source and the *b*-values for each crustal active fault source are denoted in Table 4

Crustal Active Fault Sources

Thirty-three active faults obtained by the Central Geological Survey (2010, http://fault.moeacgs.gov.tw/TaiwanFaults_2009/News/NewsView.aspx?id=3) and three blind faults by Cheng et al. (2007) were considered as crustal active fault sources (Fig. 7). Crustal active fault sources are categorized as Type I sources by Kiureghian and Ang (1977). Sources of this type usually generate earthquakes with a characteristic magnitude repeatedly within a recurrence interval. Such seismic activity does not follow the truncated exponential model, but

fulfills the characteristic earthquake model (Wesnousky 1994). For application of this model, some parameters are required (Eqs. 6, 7, and 8). The fault parameters, including segmentation, length, depth, area, the rupture mechanism, dip angle, the possible magnitude of the slip, the slip rate, the recurrence interval, the last slip time, and the magnitude of a characteristic event, were obtained from various references and are listed in Table 3. For treatment of the *b*-value, a constant *b*-value is assumed in each shallow regional source. According to the distribution of shallow

regional sources and crustal active fault sources (Fig. 7), the corresponding b -value for each source was obtained. Table 4 summarizes the b -value for crustal active fault sources.

Subduction Interface Sources

Typical interface sources take place along plate boundaries within subduction zones. Two subduction systems are located within the vicinity of Taiwan (Fig. 1). Subduction interface sources exist in both systems (Fig. 8). In the northeast subduction system, an interface earthquake with M8.2 took place in 1920 (Tsai et al. 2000) and is the largest earthquake ever recorded in T01A. m_u 's of 8.0, 8.2, and 8.4 with corresponding weights of 0.2, 0.6, and 0.2 were assumed for this source. The interface in the southern subduction system was defined according to the profiles of earthquake distribution. Three interface sources, T02A, T02B, and T02C, were defined (Fig. 8). Segmentations were defined by the bending of the accretionary wedge. Parameters for subduction interface sources are summarized and presented in Table 5. The characteristic earthquake model provides the behaviors of the seismic activity for the sources.

Subduction Intraslab Sources

The geometries of intraslab sources for subduction systems are illustrated based on the profiles of the earthquake distribution. Ten and three

interface sources were defined for the northeastern and southern subduction zones, respectively (Fig. 8). Seismic activities of the sources were determined using the truncated exponential model. The corresponding m_u 's were inferred from the maximum magnitudes of the intraslab earthquakes surrounding Taiwan and the world. The parameters and the corresponding weights for subduction intraslab sources are summarized and presented in Table 6.

Ground Motion Prediction Equations (GMPEs)

For the application of the PSHA, in addition to reliable seismogenic sources, another key factor is proper GMPEs (Encyclopedia of Earthquake Engineering: Ground Motion Prediction Equations). Lin (2009) pointed out that global GMPEs do not truly represent ground motion attenuation behaviors in Taiwan. Thus, only GMPEs obtained from the regression of strong ground motion observations in Taiwan were considered. Several studies have proposed GMPEs in order to model the attenuation behaviors for different types of earthquakes in Taiwan. For a more complete presence of attenuation behaviors, GMPEs with the form of an acceleration response spectrum (SA) are expected. In the form of SA, attenuation behaviors are presented as a response acceleration as a function of the response period. Lin (2009) considered 5,968 observations of 60 crustal earthquakes recorded by the Taiwan Strong Motion Instrumentation Program (TSMIP). GMPEs as a function of magnitude, m , are determined as follows:

$$\begin{aligned} \ln y = & C_1 + F_1 + C_3(8.5 - m)^2 \\ & + (C_4 + C_5(m - 6.3)) \ln \left(\sqrt{R^2 + \exp(H)^2} \right) \\ & + C_6 F_{NM} + C_7 F_{RV} + C_8 \ln(V_{S30}/1, 130.0), \end{aligned} \quad (10)$$

where y represents the response acceleration for PGA or SA in g ; R represents the shortest distance to the rupture surface in kilometers; F_{NM} is 1.0

Probability Seismic Hazard Mapping of Taiwan, Fig. 8

The distribution of the subduction interface and the intraslab sources illustrated by blue polygons. The surface alignments of the two trenches are presented in red

when the sources are normal mechanisms; F_{RV} is 1.0 when the sources are thrust mechanisms; V_{S30} represents the average shear-wave velocity from the ground surface down to a depth of 30 m; $F_1 = C_2(M_W - 6.3)$ for $M_W \leq 6.3$, whereas $F_1 = (-H \cdot C_5)(M_W - 6.3)$ for $M_W > 6.3$; and C_1 to C_8 and H are constants. The corresponding parameters for PGA and SA are presented in Table 7. Note that through these GMPEs, source

effects in the form of different focal mechanisms were considered and indicated that the largest amplitudes for thrust events and the smallest for normal ones were obtained based on the same magnitude and distance to the rupture surface. In order to present the reliability of these GMPEs, the corresponding standard deviations were analyzed and are presented as σ_{lny} in Table 8. These GMPEs were applied for crustal sources.

Many studies (e.g., Chan et al. 2013a) have indicated that ground motion attenuation behaviors for subduction earthquakes are different than those for crustal earthquakes. Since two subduction systems are located within the Taiwan region, as well as its vicinity (Fig. 1), the different GMPEs for both interfaces and intraslab events are considered to apply PSHAs. Lin and Lee (2008) proposed the first GMPEs for subduction events in Taiwan. In order to establish the GMPEs, they analyzed the strong motion records of subduction earthquakes obtained using TSMIP arrays and the Strong Motion Array in Taiwan Phase I

(SMARTI). The GMPEs of Lin and Lee (2008) are represented as follows:

$$\ln y = C_1 + C_2 m + C_3 (R + C_4 e^{C_5 m}) + C_6 H + C_7 Z_t, \quad (11)$$

where y represents the response acceleration for PGA or SA in g , R represents the hypocentral distance in kilometers, H represents the focal depth in kilometers, Z_t represents the subduction zone earthquake type ($Z_t = 0$ for interface earthquakes, whereas $Z_t = 1$ for intraslab earthquakes), and C_1 to C_7 are constants. The parameters and their corresponding standard

deviations for PGA and SA are presented in Table 8 and indicate the largest amplitude for intraslab events than interface ones when the magnitude and the hypocentral distance are the same. Since the GMPEs of Lin and Lee (2008) are among the only GMPEs from the regression of ground motion observations in Taiwan, they were applied to this study.

Seismic Hazards in Taiwan

The Hazard Maps

By considering all of the seismogenic sources, the corresponding parameters, and the GMPEs,

a PSHA was applied for Taiwan. The spatial distributions of seismic hazards were evaluated in the form of a seismic hazard map. The seismic hazards for 10 % (475-year return period) and 2 % (2,475-year return period) of the probability of exceedance for 50 years are presented (Fig. 9). The results suggest that seismic hazards in Taiwan are mainly contributed by active fault sources. The highest seismic hazard levels were determined from the Western Foothills to the Coastal Plain. A >1.0 g hazard for a 10 % probability of exceedance for 50 years was estimated near the Chiayi blind fault and the Tachienshan Fault (Fig. 9a). A high hazard was also evaluated along the eastern coastline and can be attributed

to crustal active fault sources with short recurrence intervals along the Longitudinal Valley (Fault ID 26–33 in Table 3). In contrast, in northern Taiwan, a low hazard level was obtained. Although the Sanchiao Fault is located in this region, the recurrence intervals of the fault are rather long (in between 614 and 2,511 years).

The Hazard Curves

In order to represent the probability of annual exceedance as a function of ground motion level for different response periods, hazard curves are presented. The hazard curves were evaluated for the six municipalities, i.e., the Taipei, New Taipei, Taoyuan, Taichung, Tainan, and Kaohsiung

Cities, respectively (Fig. 10). The hazard curves for PGA and the response period of 0.3 and 1.0 s are obtained. Since some active faults are close to the Tainan and Taichung Cities (Fig. 9), higher hazards were determined. By contrast, the hazards in the Taipei, New Taipei, Taoyuan, and Kaohsiung cities are relatively low because of they are further away from crustal active fault sources with short recurrence intervals.

Discussion and Conclusions

A Comparison to Other PSHA Results

Probabilistic seismic hazards imparted by different seismogenic sources for the Taiwan region

Probability Seismic Hazard Mapping of Taiwan, Fig. 9 The seismic hazard maps in (a) a 10 % (a 475-year return period) and (b) a 2 % (a 2,475-year return period) probability of exceedance for 50 years

were assessed. Higher hazards were determined along active faults in the Coastal Plain and the Longitudinal Valley. The pattern can be associated with the distribution of seismic activity in Taiwan. The pattern is similar to those obtained from previous studies (e.g., Cheng et al. 2007). In more detail, hazard peaks were evaluated near crustal active fault sources with short recurrence intervals. The results were similar to those obtained from other PSHA studies (e.g., Campbell et al. 2002; Cheng et al. 2007), which also considered the hazards imparted by active faults. The pattern can be attributed to the behaviors of GMPEs (Lin 2009), illustrating the significance

of larger ground shakings surrounding regions close to earthquake epicenters or rupture faults. The attenuation behavior is similar to observations of the 1999 Chi-Chi, Taiwan, earthquake. The shake map of this earthquake indicated significant high ground shakings in the form of PGA in the vicinity of the Chelungpu Fault, which ruptured during the coseismic period.

The Importance of the Short-Term Probabilistic Seismic Hazard Assessment

Recently, the concept of a traditional PSHA has been called into question. One of the standard procedures for traditional PSHAs is the

Probability Seismic Hazard Mapping of Taiwan, Fig. 10 The probability of annual exceedance as a function of hazard curves for PGA and the response period of

0.3 and 1.0 s for the six municipalities. The *solid* and *dashed lines* represent mean and two standard deviations of seismic hazards, respectively

construction of return periods for characteristic earthquakes that are independent of one another (see section “[The Declustering Process](#)” for details). Thus, an earthquake should be declustered prior to its incorporation for a PSHA. However, some recent cases have determined disadvantages for traditional PSAs. For example, the M_w 6.3, 21 February 2011, Christchurch earthquake can be regarded as an aftershock of the M_w 7.1 Darfield earthquake that took place on 4 September 2010. The Christchurch earthquake caused severe damage in downtown Christchurch due to a closer epicentral distance. Additionally, not only can aftershocks lead to devastating seismic hazards, but the next earthquake could expand hazards. An earthquake with a M_w 7.4 took place off the Pacific coast of Tohoku, Japan, on 9 March 2011. Due to its distance from urban regions, the resulting damage from this earthquake was negligible. Fifty-one hours after the earthquake (on March 11), a M_w 9.1 earthquake took place in the vicinity and resulted in disasters in Japan. Seismic hazards may also result from several events within an earthquake sequence. Based on spatial and temporal relationships, the 1904 Toulou and the 1906 Yanshuigang earthquakes can be regarded as a foreshock and an aftershock of the 1906 Meishan earthquake (Fig. 2), respectively. However, all three earthquakes caused severe disasters. The case indicates the importance of the seismic hazards imparted by each event in an earthquake sequence and raises the unsuitability of traditional PSAs (Chan et al. 2013b). Such instances indicate the importance of an earthquake sequence in respect to seismic hazard evaluations and suggest the reevaluation of seismic hazards immediately following large earthquakes.

Several studies have recognized disadvantages in traditional PSAs and have considered a time dependency for PSAs. For example, Chan and Wu (2012) and references therein estimated the temporal evolution of the seismicity rate and assessed seismicity hazards as a function of time. The feasibility of this approach has been tested using applications to several cases in Taiwan (e.g., Chan et al. 2013a, b).

The Applicability of PSHA Results and Seismogenic Parameters

An assessment of seismic hazards had been widely applied for each administrative region in Taiwan. In addition, hazard curves for the six municipalities were evaluated. According to the results, the probability of annual exceedance as a function of ground motion level for different response periods was presented. They would be valuable to lawmakers for determining building codes and to decision-makers for the site selection of public structures.

In addition, based on the PSHA results, further applications in respect to seismic hazard mitigation can be assessed (e.g., probabilistic seismic risk assessment). A risk assessment is presented as the probability that a given loss of property and human life exceeds a specific value during a time period. For its application, seismic hazards, exposure (distribution of population or construction), and a corresponding vulnerability are incorporated. The result could be of benefit to decision-makers for territorial planning.

The parameters implemented for the PSHA were acquired through the integration of state-of-the-art information regarding the tectonic setting, geology, geomorphology, earthquake catalog, geophysics, and the ground motion attenuation. The information could be used as a reference for an additional PSHA. For example, these parameters will be regarded as a branch in the logic tree approach for the Committee of Taiwan Earthquake Model (TEM, <http://tec.earth.sinica.edu.tw/TEM>). TEM is working on a seismic hazard map for the entire region of Taiwan. In the meantime, the work can also be incorporated within the Global Earthquake Model (see entry “The Global Earthquake Model (GEM)”), integrated by several research institutes, insurance, and reinsurance enterprises in order to evaluate seismic hazards around the world. Through collaboration with organizations on different scales and with different individuals, the GEM is expected to establish uniform and open standards for calculating and communicating earthquake hazards and risks worldwide.

Summary

A probabilistic seismic hazard assessment is implemented to the region of Taiwan. Seismogenic sources, which may result in seismic hazards, were divided into the following categories: shallow-crust regional sources, deep-crust regional sources, crustal active fault sources, subduction intraslab sources, and subduction interface sources. By further considering ground motion prediction equations for different types of sources and site conditions, hazard maps in Taiwan and hazard curves in the six municipalities were assessed.

Radiocarbon calibration

Introduction

Paleoseismology needs a chronological framework for past seismic events. Dating information can come from a variety of different sources, but primarily comes from stratigraphy combined with scientific dating techniques applied either to the seismic record or associated through major environmental signals (e.g., glacial-interglacial cycles).

For timescales spanning the last 50,000 years, radiocarbon dating is one of the most widely used dating techniques. It can be applied to organic material, biominerals (such as shell and coral), and in some cases to carbonate deposits and is therefore possible in a wide range of different environments. It is complementary to other techniques such as optically stimulated luminescence

dating (OSL), uranium-series dating, and argon-argon dating, relevant to different material types. Unlike those techniques, however, radiocarbon dating is a method that requires calibration against known-age samples dated by a different method. One implication of this is that the correct application of radiocarbon dating in seismology, as in other fields, often requires an understanding of the relevant parts of the carbon cycle. As with any dating technique, accurate interpretation of the data always relies on a careful examination of the relationship between dated samples and the events under investigation.

One tool that has become increasingly useful for the combination of information from stratigraphy and scientific dating techniques is Bayesian age modelling. These methods are most often applied with radiocarbon dating, but are also relevant to other dating techniques and are sufficiently flexible to be used with multiple methods. These Bayesian models are ideally suited to the generation of quantitative estimates of dates and intervals in paleoseismology.

Radiocarbon Dating

Radiocarbon dating (Libby et al. 1949) is a method that covers about the last 50,000 years. Primarily applicable to organic material, in principle, it can be applied to any material that draws its carbon directly, or indirectly, from the

Radiocarbon Dating in Paleoseismology,

Fig. 1 This schematic of the carbon cycle explains the distribution of radiocarbon through the different parts of the earth system. The ratios are highest in the stratosphere with a gradient down through to the geosphere. In practice, levels throughout the troposphere and (terrestrial) biosphere are very similar. The ratios are depleted by about 5 % in the surface oceans, and the geosphere has radiocarbon ratios below detection limits

atmosphere. The precision of the method is typically of the order of ± 100 years for the last few 1,000 years rising to the order of $\pm 1,000$ years at its limit. For optimum precision, samples should contain >1 mg of carbon, but samples smaller than this (by at least one order of magnitude) can be dated in some circumstances with reduced precision.

Radiocarbon is a cosmogenic isotope, produced in the upper atmosphere. It is incorporated into almost all living organisms, but once they die and stop taking up carbon from the atmosphere, the radiocarbon content decays away with a half-life of about 5,730 years.

Unlike some dating techniques (such as uranium-series dating on speleothems or corals), radiocarbon is not an absolute dating technique, but relies on the comparison of radiocarbon measurements on samples to those made on samples of known age (a process called calibration). In order to understand the limitations and

potential of the method, it is important to understand how the method works in some detail.

Radiocarbon in the Global Carbon Cycle

Radiocarbon is formed by the action of high-energy cosmic rays, largely from outside the solar system, on the upper atmosphere. The flux of these cosmic rays varies for a number of reasons, including changes in solar activity and in the earth's magnetic field.

Once produced the radiocarbon is quickly oxidized to $^{14}\text{CO}_2$. This radiocarbon-labelled carbon dioxide is mixed throughout the atmosphere through the atmospheric circulation. This mixing is very rapid within each hemisphere, but not so rapid across the equator. As part of the global carbon cycle (see Fig. 1), carbon dioxide exchanges between the surface oceans and the atmosphere and is also absorbed by photosynthesis into green plants and thereby into the biosphere.

The overall effect of the transport of carbon through the carbon cycle is that:

- The $^{14}\text{C}/^{12}\text{C}$ ratio is fairly uniform within each atmospheric hemisphere. There is a small-amplitude annual oscillation of the order of 0.4 % in the preindustrial era (Kromer et al. 2001) with longer-term fluctuations due both to changing production rates and changes in the carbon cycle itself (particularly ocean circulation and ventilation). The Southern Hemisphere is typically depleted in radiocarbon compared to the Northern Hemisphere by about 0.5 %.
- Living organisms that take their carbon directly from the atmosphere share the same radiocarbon content, though there is usually some isotopic fractionation between the atmosphere and biosphere, which can be corrected for by measuring the stable isotope ratio $^{13}\text{C}/^{12}\text{C}$. Reported radiocarbon dates are normally corrected for fractionation effects. Green plants usually form the lowest level in the food chain, and thus the radiocarbon throughout the biosphere is the same. However, plants and animals that live for significant periods might not be fully equilibrated with the atmosphere, and this has to be considered when interpreting radiocarbon dates.
- The surface oceans are depleted in radiocarbon compared to the atmosphere by ~5 %. The depletion in the deep oceans is much greater and highly dependent on local ocean circulation. Because of the complexities of the ocean system, the exact relationship between the surface oceans varies both spatially and temporally, making the dating of samples from the marine environment more complex.
- Carbon-containing geological formations made ultimately from living organisms (such as carbonates and coal) are sufficiently old that they do not contain any measurable radiocarbon.
- Rivers, lakes, streams, and groundwater can all contain a mixture of carbon from the atmosphere and from geological substrates. For this reason, samples from such systems will often be depleted in radiocarbon compared to the

atmosphere by amounts that have to be locally determined. This affects the radiocarbon dating of speleothems and organic deposits deriving their carbon from fully aquatic food systems.

Samples for Radiocarbon Dating

Information about the carbon cycle has a direct influence on the optimum choice of samples for dating seismic events. There are three main criteria for sample selection (assuming availability of suitable material), which are generally common to all applications of radiocarbon dating (Waterbolk 1971). These are: uncertainty in inbuilt radiocarbon age, association of the sample with the event, and state of preservation of the samples:

- Inbuilt radiocarbon age can be understood from the carbon cycle. Short-lived terrestrial plant remains, such as leaves, seeds, and small stems, normally have carbon directly from the atmosphere (via photosynthesis); these are ideal material for dating. Animal bones may have inbuilt age of the order of a few years to a few decades. Such offsets are often insignificant, and this makes these good materials for dating, but often unavailable in sites where seismic activity is clearly recorded. Wood from long-lived tree species is more problematic, as it can have inbuilt age of decades to centuries; in such cases, dendrochronological analysis might be appropriate, or outer rings can be selected for dating if available. Aquatic and marine environments are themselves depleted in radiocarbon and so have inbuilt radiocarbon age; it can be possible to correct for this, but in so doing, some precision is usually lost.
- Association between the sample and the seismic event of interest is clearly critical. In part, this comes down to stratigraphy, but also depends to some extent on the sample material itself. Fragile materials such as plant fragments are likely to be in their primary deposits because they are unlikely to survive significant reworking. Well-preserved plant macrofossils are therefore to be preferred over

charcoal fragments, which might well remain within sedimentary deposits during transport. In archeological contexts, articulated bones are another sample type where the nature of the sample indicates primary deposition. When dating raised shorelines, which can be useful for measuring tectonic uplift, marine species that are known to live close to the surface are best as they are less likely to date from previous uplift events (see, e.g., Shaw et al. 2010).

- For accurate dating samples also need to be well preserved. Most radiocarbon pretreatment methods work on the basis of recovering large molecules that remain in the sample from the living organism. These might be cellulose in plant remains, collagen in bone, or primary carbonates in the case of shell. Large organic molecules decay with time and with changes in water content of the sediments, and carbonates can be recrystallized over time. For these reasons, finding a well-preserved material can be a challenge.

There are often competing considerations in the choice of materials. For example, the optimum type of sample may not be available in close association with the evidence for the seismic event. In some instances, only poorly defined “organic carbon” from sediments is available for dating, which inevitably introduces considerable uncertainty into the dating, since there is no single link to a living organism, or even a coeval group of organisms.

Measurement of Radiocarbon

Radiocarbon dating has two main stages: pretreatment and measurement.

Pretreatment is the chemical extraction of material known or presumed to be from the original organism. It is necessary to remove contaminants that come from the environment, which might be of a very different age. In general, these methods work by purification of stable large molecules (cellulose, collagen, chitin), mineral complexes such as shell, or reduced carbon (in the form of charcoal). With the exception of

reduced carbon, these are carbon-containing materials, which would have been part of the original living organism and should therefore have a carbon content reflecting that of the prevailing environment. Reduced carbon is assumed to derive from such large molecular components and thus also provide material suitable for dating. Pretreatment usually involves using acid (for removal of deposited carbonates or dissolved carbon dioxide) and alkali (for the removal of humic acids). However, particularly for accurate dating of older samples, there are now much more elaborate pretreatment methods available. It is important to discuss the specific requirements with a radiocarbon laboratory with suitable experience.

The measurement process gives the isotope ratio of the sample. To correct for fractionation through the carbon cycle, it is necessary to measure both the $^{14}\text{C}/^{12}\text{C}$ and the $^{13}\text{C}/^{12}\text{C}$ ratios. The $^{13}\text{C}/^{12}\text{C}$ is normally measured using a stable isotope mass spectrometer, and the $^{14}\text{C}/^{12}\text{C}$ can either be measured by decay counting (gas or liquid scintillation counting, both of which need sample sizes of the order of 1 g) or by accelerator mass spectrometry (AMS, which requires a sample size of the order of 1 mg). In both cases, the radiocarbon date reported should contain the following information:

- A laboratory code, which identifies the laboratory and gives the information necessary to check any analytical details at a later stage.
- The nominal radiocarbon “age” calculated using the Libby half-life of 5568a with a 1σ standard uncertainty (or alternatively a ratio compared to the atmospheric ratio for 1950). This result should already be corrected for any isotopic fractionation. The units for radiocarbon dates are normally BP (sometimes written as ^{14}C BP) where the BP means “before present,” “present” being AD 1950.
- The $^{13}\text{C}/^{12}\text{C}$ ratio, expressed as $\delta^{13}\text{C}$ relative to the PDB standard.

These three components should always be reported as primary data with any study using

Radiocarbon Dating in Paleoseismology, Fig. 2 This shows a typical calibration plot for a single radiocarbon date. The radiocarbon measurement in this case is 3010 ± 30 BP (uncertainty at 1σ). The *red* distribution illustrates the uncertainty in this measurement on the radiocarbon date scale. The *blue* curve is the atmospheric calibration curve for this time period (with lines at $\pm 1\sigma$).

The *gray* probability distribution on the calibrated date axis shows the probability that the sample is any particular age. This can then be summarized into ranges either at the 68.2 % level (the most likely dates) or the 95.4 % level (ranges within which the date very likely lies). Note that the ranges are split and the distribution is multimodal; this is typical for radiocarbon calibrations

radiocarbon data. It is not sufficient to report the calibrated date (see next section) because calibration curves are updated periodically, and it is not possible to get back to the original measurement data from the calibrated date.

Calibration of Radiocarbon Dates

A radiocarbon “date,” as reported by a radiocarbon laboratory, is really just as an isotope ratio, and the conversion to a notional radiocarbon “date” is a convention that arose to put the measurement in a broad chronological context. The half-life used is that estimated by Libby and now known to be too low. The date is based on the assumption that the levels of radiocarbon in the atmosphere have remained constant over time, so to convert this into a real date, it is necessary to calibrate it against material of known age. To do this, it is necessary to use a calibration curve, which is a compilation of a very large number of radiocarbon measurements on material from records with independent chronologies. For the Holocene and Late Glacial

periods, these chronologies are based on dendrochronology; for earlier periods, the main control is uranium-series dating.

There are two main calibration curves, one for the atmosphere (currently IntCal13) and one for the oceans (Marine13) with details published in Reimer et al. (2013). These latest curves cover the full effective range of the radiocarbon dating technique (50,000 years).

When calibrating a radiocarbon date, it is first important to determine the reservoir from which the sample draws its carbon (Northern Hemisphere Atmosphere, Southern Hemisphere atmosphere, ocean, etc.). For the oceans, it is also necessary to know how different the local ocean radiocarbon levels are from the ocean average. A useful reference for this is the Marine Reservoir Database (<http://calib.qub.ac.uk/marine/>), which provides a compilation of preindustrial values. It should be noted, however, that changes in ocean circulation over time make these values inherently uncertain; this is especially true when considering pre-Holocene dates.

Calibration of a single radiocarbon date can be carried out using a number of different software packages – two common ones being Calib (<http://calib.qub.ac.uk/calib/>) and OxCal (<http://c14.arch.ox.ac.uk/OxCal.html>). Figure 2 shows an example calibration using OxCal and explains some of the main elements of the process.

Constraining Dates of Seismic Events

Using radiocarbon dates for the study of seismic events requires particular attention to the association between the samples that have been radiocarbon dated and the seismic event of interest. There are a number of different approaches that can be taken depending on the particular context.

The most straightforward approach is to try to find samples that relate very directly to the seismic event itself. Examples of this approach could be debris from a seismic event (e.g., destruction level in a human occupations site), or debris from a tsunami event, or marine material exposed by a tectonic uplift event (raised shoreline). In almost all cases, the material being dated will actually predate the seismic event, and efforts are made to ensure that the samples are not likely to predate the earthquake very significantly (see section on “[Samples for Radiocarbon Dating](#)”).

If there is more than one radiocarbon date associated with the seismic event and if all of the events can be assumed to come from within a year or so of the event (well within 10 years), then the different measurements can be combined before calibration. This might be the case, for example, in a tsunami or destruction event that has large quantities of short-lived plant material for dating. Before any such combination, the spread of measurements should be checked using a χ^2 test (Ward and Wilson 1978).

In most cases, however, it is very difficult to date a seismic event directly, and often all that can be done is to obtain dates that bracket the event in some way. If only one date is available, there is little that can be done other than calibrate it and discuss the implications

for the event in relation to this one constraint. If there are many dates, then it is possible to use a Bayesian statistical model to combine all of the available information and get quantitative estimates for the dates of the seismic events themselves.

Bayesian Modelling of Chronologies

When dealing with radiocarbon dates, Bayesian statistics provides a useful framework for the integration of information from different sources and is widely used in archeology and environmental science. This is partly because of the non-normal nature of the uncertainties in calibrated radiocarbon measurements but also because such methods are very flexible and allow the inclusion of many different kinds of underlying model.

When dating seismic events, there are three main types of situation:

- Radiocarbon dates provide constraints for a single seismic event of interest.
- A sequence of seismic events is constrained by radiocarbon dates.
- Seismic events are recorded in a well-behaved sedimentary record, which can be dated by radiocarbon.

Each of these different possibilities requires slightly different approaches and so will be considered individually. There are a number of computer programs available for Bayesian analysis with stratigraphic constraint such as BCal (Buck et al. 1999) and OxCal (Bronk Ramsey 2009). For age-depth modelling, the same is also true with software such as OxCal (Bronk Ramsey 2008), BChron (Haslett and Parnell 2008), and Bacon (Blaauw and Christen 2011). Because OxCal uses a metalanguage, which makes it easy to specify models with text code, and because it can be used for both constrained modelling and full age-depth models, the examples given below are illustrated with that package. There is a primer on the use of OxCal for paleoseismology (Lienkaemper and Bronk Ramsey 2009).

Radiocarbon Dating in Paleoseismology, Fig. 3 The stratigraphy of deposit related to a seismic event (*E1*) is shown on the *left*. In the center are three different models that could be applied (*A*, if there is only overlying material; *B*, if there is only underlying material, older than the

event; *A* and *C*, where there is both). All models assume a concentration of dated samples close to the event. On the *right* is an outline of the OxCal code for the case where there is material below and above the event

Constraints on a Single Seismic Event

The first situation to be considered is the case of a single seismic event. As discussed above, it is unusual to be able to date such an event directly. Quite often the dates associated with the event must all be older than the event because the samples are from material that was growing some time before. The model needs to take into account that most such material will be close in age to the event, but there is the possibility of occasional samples being substantially older. The most appropriate model for this scenario is one that treats the dated events as an exponential distribution through time (with an unknown time constant). Another less frequent situation is where there is only material overlying the seismic event to date. Ideally having both would constrain the event more precisely. Figure 3 shows such situations schematically. The program OxCal provides a metalanguage for the formulation of such models (Bronk Ramsey 2009). Note that in all cases the OxCal code definition follows the order of the events (from oldest to youngest) and therefore is reversed compared to the stratigraphic order.

Stratigraphic Sequences

The next situation is where there are several seismic events represented in the deposit. If the depositional processes are similar throughout, it is reasonable to assume that the dated samples and seismic events are all part of a sequence of events that have been sampled randomly. In this case, no assumptions are made about the stratigraphic sequence of samples between the seismic events. Figure 4 shows a schematic of such a situation and explains how such a model might be constructed in OxCal. Such a model will be realistic as long as the dates are randomly scattered through the sequence.

In practice, radiocarbon samples are often concentrated in particular parts of a sedimentary sequence, and this might well reflect underlying changes in the sedimentation processes. In such cases, the models should have “boundaries” which define the changes in sedimentation. In some cases, it may be that the seismic events correspond with significant changes in sedimentation type, and in this case the seismic events should be classed as boundaries. Such a situation is shown in Fig. 5, where there is a concentration

Radiocarbon Dating in Paleoseismology, Fig. 4 A sedimentary sequence with a scatter of radiocarbon dates in three groups separated by two seismic events, *E1* and *E2*, is illustrated on the *left*. The central panel shows a schematic for the model applied in this case, the underlying assumption being a random scatter of events throughout the sequence. The *right-hand* panel shows

the main elements of an OxCal model implementation; note that in this case, the radiocarbon dates are nested within “phases” implying that there is no information about the relative order within each group. This is similar to the example given in (Lienkaemper and Bronk Ramsey 2009)

of radiocarbon samples in an organic layer underlying each seismic event. The use of boundaries ensures that the concentration of radiocarbon dates in parts of the sequence does not itself bias the model as a whole.

Deposition Models

Another type of Bayesian model that is useful for paleoseismology is an age-depth model for sedimentary sequences. Such models can be used when there are a series of radiocarbon dates in a single sediment column, with depth information. Most commonly, these are used for cores, but could also be applied to other types of section if a single depth scale can be defined. Like other Bayesian models, there needs to be a mathematical model for the deposition process. One such model is the Poisson process model implemented in OxCal. In this model, the assumption is that the deposition is random which allows for flexibility in an otherwise

approximately uniform deposition (Bronk Ramsey 2008). The degree of flexibility can be determined by the model, using the available data (Bronk Ramsey and Lee 2013). Figure 6 outlines the main aspects of such a model, in this case assuming that the sedimentary processes do not change significantly down the core. As with the sequences described above, boundaries can be introduced to split such a model into sections if there are major lithostratigraphic changes, which might imply an abrupt change in sedimentation rate.

Recurrence Information

So far, the discussion here has centered on retrieving quantified date information for seismic events. However, in many instances, it is equally important to get information about the interval between events, especially when estimating risk. Fortunately, the Bayesian models allow this information to be extracted and summarized.

Radiocarbon Dating in Paleoseismology, Fig. 5 The situation illustrated here is similar to that in Fig. 4, except that the dated samples are no longer randomly scattered and there is a clear stratigraphic boundary within the levels *B* and *C*. The central panel shows a schematic for the most appropriate model, which is divided up into levels within which the deposition of samples is more

likely to be random. The *top* and *bottom* of each of the organic layers that contain the concentration of radiocarbon samples are defined as boundaries in the model; in this case, this also coincides with the seismic events *E1* and *E2*. The *right-hand* panel shows, in outline, how such a model might be constructed in OxCal

There are two main properties of interest: the mean recurrence interval and the recurrence error distribution (Lienkaemper and Bronk Ramsey 2009).

- The mean recurrence interval can be calculated if the difference in date between the first seismic event (e.g., E_n) and the final seismic event ($E1$) is known and the number of events (n). The mean recurrence interval is just given by $(E1 - E_n)/(n - 1)$. If extracted from a Bayesian model, this property will have a probability distribution which gives the uncertainty associated with this mean (but not the variability in the recurrence intervals).
- The variability in recurrence rates is also of interest. However, there is often considerable uncertainty in each of the successive recurrence intervals, and it is impossible to distinguish between this uncertainty and the actual variability in recurrence interval. The best

that can be done is to calculate each of the intervals (e.g., the interval between the last two events given by $I1_2 = E1 - E2$) and then to superimpose all of these to obtain a distribution using the sum function in OxCal (see details in Lienkaemper and Bronk Ramsey 2009 and Fig. 7). This summed distribution is a convolution of the original real recurrence interval distribution and the uncertainty in measuring the age differences between successive events.

Summary

Radiocarbon is a powerful dating technique, but its correct application requires a detailed consideration of the different parts of the method. In particular, the calibration of radiocarbon dates can only be carried out with a good understanding of the relationship of the dated samples to the global carbon cycle. Samples that derive their

Radiocarbon Dating in Paleoseismology, Fig. 6 Lake and marine cores provide a useful source of evidence for past seismic events. Where radiocarbon is used to date such cores, age-depth models can be used to integrate the information from the dated samples and the depths of the samples and events of interest. The central panel shows schematically the underlying assumption for a simple Poisson process model, where randomly varying

sedimentation continues over the whole sediment sequence. The *right-hand* pane shows the outline of the model definition within OxCal assuming the depth is given in cm, and depth output is required at cm intervals; if the depth is given in m, the first line of the code is different (see Bronk Ramsey and Lee 2013, for more details)

```
// Calculate intervals between seismic events
// and summed interval distribution (ID)
Sum("ID")
{
  I1_2=E1-E2;
  I2_3=E2-E3;
  I3_4=E3-E4;
};
// Calculate mean recurrence interval
RI=(E1-E4)/3;
```

Radiocarbon Dating in Paleoseismology, Fig. 7 Example of OxCal code (from Lienkaemper and Bronk Ramsey 2009) for calculating the mean recurrence

interval (RI) and the recurrence error distribution (ID) for a model where there are four seismic events $E1$, $E2$, $E3$, and $E4$

carbon fairly directly from the atmosphere are easiest to calibrate, whereas calibrating samples from marine environments requires more specific local environmental information.

Alongside developments in radiocarbon dating itself, comprehensive methods have been developed for the integration of chronological information into Bayesian age models. They are

most often applied to studies involving radiocarbon dating but can also be used with other dating techniques. Although these have been developed, initially for archeology and more recently for paleoenvironmental studies more generally, they are well suited to quantifying characteristics of seismic systems.

Random Process as Earthquake Motions

Luigi Carassale

Ground motion; Random process

Introduction

Earthquakes appear as an erratic phenomenon and are considered as unpredictable, at least from a deterministic point of view. They involve a randomness that is at least twofold involving the occurrence of earthquakes (when and where they appear) and the ground motion that they produce. An individual earthquake arrives in a random place on earth (even if some places are more likely to see a seismic event than others), appears at a random time and has variable intensity. On the other hand, the ground motion generated by the earthquake has random amplitude (e.g., peak acceleration), duration and spectral characteristics. Besides, the ground motion is variable in space due to a number of physical phenomena related to the propagation of the seismic waves. This intrinsic randomness suggests using probabilistic tools to represent and characterize earthquakes.

Of the two faces of the problem mentioned above, only the second one is considered here,

namely the stochastic characterization of the ground motion, given that an earthquake occurs at a specific site. The definition of stochastic models for this purpose have been of interest for a long time and several studies have been presented in the scientific literature mostly in the 1960s and 1970s of the last century.

Stochastic models for the representation of seismic ground motion are used to simulate artificial seismic acceleration time histories with specified characteristics, which may be employed in the framework of the Performance-Based Earthquake Engineering. The most common choice in this context is the use of natural acceleration records that are scaled and applied, as excitation, to a numerical model of the structure. This approach has several drawbacks including the scarce availability of natural recorded ground motions for the specific earthquake characteristics of interest (magnitude, distance, type of faulting, site conditions, etc.), the doubtful meaningfulness of the scaling procedure (e.g., Grigoriu 2011) and the questionable choice of the intensity measure used as reference for scaling.

Artificial ground motions can be obtained through Monte Carlo simulation from generative stochastic models that are parametrized with quantities that may be related to the site and earthquake characteristics. Simulated ground motions can be used as a surrogate of measured ones to calculate the dynamic response of a structure. Besides, the stochastic model can be directly used to predict the probabilistic response of the structure within the framework of the stochastic structural dynamics, whenever the structure is simple enough to enable this approach.

Seismic ground motions are randomly variable in time and space and are commonly modeled as random processes. As far as their temporal variability is concerned, the observation of recorded time histories of ground acceleration immediately reveals their nonstationary nature in terms of amplitude. A more careful analysis also reveals a significant variability of their harmonic content with the time. Figure 1 shows, as an example, a ground motion measured in Kobe, Japan, during the 1995 earthquake. The variation in time of the amplitude is

well evident observing the acceleration time history (Fig. 1a), while the variation of the harmonic content can be observed in the wavelet map (Fig. 1b).

Temporal nonstationarity can be easily modeled by multiplying a stationary process by a time-varying envelope function, while the modeling of spectral nonstationarity is definitely more complicated. Several researchers (e.g., Rezaeian and Der Kiureghian 2008) believe that, both these effects may be important, in particular when dealing with the analysis of nonlinear structures. In this case, indeed, the evolution of the dynamic characteristics of the structure due to degradation may match in an unfavorable way with the variation of the spectral content of the seismic input. As far as the spatial variability is concerned, several studies demonstrated that the earthquake ground motion measured in different points of a site may be significantly different due to a series of physical reasons. This difference increases as the mutual distance of the points increases and may have an important impact on structures that have large planimetric size such as bridges and pipelines.

A large number of stochastic models to represent the ground motion in a single point have been developed and described in several review papers (e.g., Liu 1970; Ahmadi 1979; Shinozuka and Deodatis 1988; Kozin 1988; Conte and Peng 1997). The existing stochastic models can be classified into four categories: (a) processes obtained by passing a Gaussian white noise through a filter, with subsequent modulation in time to achieve temporal nonstationarity; (b) processes obtained filtering an amplitude-modulated Gaussian white noise; (c) processes obtained through the amplitude modulation of a filtered Poisson process; (d) processes obtained by linear filtering of an amplitude modulated Poisson process; (e) processes realized as the output of time-variant linear filters driven by a Gaussian white noise. Models of type (a) are the simplest ones and are discussed in the following. Their main limitation involves their inability of reproducing time-variable frequency contents. Models of type (c) and (d) are rather flexible being able to produce

Random Process as Earthquake Motions,

Fig. 1 Time history (a) and wavelet map (b) of a ground acceleration (Kobe 1995)

amplitude and spectral nonstationarity, as well as non-Gaussian probability distributions. On the other hand, they require a quite difficult calibration process and it is difficult to relate model quantities with physical parameters obtained a priori from the characteristics of the site. The advantage of models type (e) is in their ability in modeling both temporal and spectral nonstationarity within the framework linear filtering (Rezaeian and Der Kiureghian 2008). An example of these models is briefly reported.

The models available to represent the spatial variability of the seismic motion are essentially expressed in terms of coherence function (e.g., Der Kiureghian 1996), therefore can be easily casted into the framework of models type (a).

Stochastic Models for the Seismic Ground Motion

According to the models type (a) defined above, the ground acceleration $u(t)$ due to a seismic event is modeled as a zero-mean random process expressed in the form:

$$u(t) = A(t)y(t) \quad (1)$$

where $y(t)$ is a zero-mean stationary Gaussian random process (function of the time t) whose Power Spectral Density (PSD) function is $S_y(\omega)$, ω being the circular frequency; $A(t)$ is a slowly varying modulation function. Within the hypothesis that the variation of $A(t)$ is slow with respect

Random Process as Earthquake Motions,

Fig. 2 Time modulating functions. Equations 3, 4, and 5; $b_1 = 0.1$, $b_2 = 0.4$, $b = 0.2$, $m = 1$ or 2 , $t_1 = 4$ s, $t_2 = 12$ s

to the characteristic time scale of $u(t)$, the ground acceleration $u(t)$ can be represented through the Evolutionary Power Spectral Density (EPSD) function given as:

$$S_u(\omega, t) = |A(t)|^2 S_y(\omega) \quad (2)$$

A random process in the form of Eq. 1 is referred to as a uniformly modulated process; the amplitude of its PSD changes in time according to Eq. 2, but the harmonic distribution of its power is time-invariant.

A number of models for the modulating function $A(t)$ have been proposed, mostly in the 1960s and 1970s of the last century. Some of these models are reported here below (Shinozuka and Sato 1967; Iwan and Hou 1989; Jennings et al. 1969).

$$A(t) = A_0(e^{-b_1 t} - e^{-b_2 t}) \quad (3)$$

$$A(t) = A_0 t^m e^{-bt} \quad (4)$$

$$A(t) = \begin{cases} (t/t_1)^2 & t \leq t_1 \\ 1 & t_1 < t \leq t_2 \\ e^{-b(t-t_2)} & t > t_2 \end{cases} \quad (5)$$

where b, b_1, b_2, m, t_1, t_2 are positive constants and A_0 is usually calibrated to obtain the maximum value of $A(t)$ equal to unity. Figure 2 shows a

qualitative comparison of the four modulation functions obtained through Eqs. 3, 4, and 5.

As far as the random process $y(t)$ is concerned, a popular PSD model attributed to Kanai (1957) and Tajimi (1960) represents the ground acceleration as the absolute acceleration of a linear single-degree-of-freedom (sdof) system excited by a white noise. In this sense, the oscillator represents the terrain and the input white noise is the acceleration at the faulting point. Under this hypothesis the PSD of the process $y(t)$ is given as:

$$S_y(\omega) = S_{KT}(\omega) = \frac{(\omega_K^4 + 4\xi_K^2 \omega_K^2 \omega^2)}{(\omega_K^2 - \omega^2)^2 + 4\xi_K^2 \omega_K^2 \omega^2} S_0 \quad (6)$$

where the model parameters ω_K and ξ_K can be interpreted as natural frequency and damping ratio of the terrain; S_0 is a constant parameter scaling the variance of the random process and is related, in some sense, with the intensity of the earthquake. For the case of stiff terrains ω_K is about 4π – 5π and ξ_K is about 0.6–0.7.

A clear drawback of the Kanai–Tajimi (KT) model is its inconsistency in the low-frequency range due to its finite value for ω tending to zero. This implies that the PSD of displacement (and velocity) diverges giving rise to an unlimited amplitude of the ground displacement.

Random Process as Earthquake Motions,

Fig. 3 PSD of the parent stationary process $y(t)$. KT model (*solid line*) CP model (*dashed line*). Model parameters are given in Table 1. The ordinate for Mexico City earthquake is divided by 10

Random Process as Earthquake Motions, Table 1 Example of parameters for KT and CP models (after Yeh and Wen 1990)

Earthquake	ω_K (rad/s)	ζ_K	ω_P (rad/s)	ζ_P	S_0 (m ² s ⁻³)
El Centro	19.0	0.65	2.0	0.6	$2.9 \cdot 10^{-3}$
Taft	20.0	0.65	1.0	0.5	$2.8 \cdot 10^{-3}$
Mexico City	4.2	0.1	0.23	0.1	$3.3 \cdot 10^{-3}$

This problem can be easily circumvented by introducing a high-pass filter in series with the filter defining the KT model. A popular model obtained in this way is attributed to Clough and Penzien (1975) and is defined as:

$$S_y(\omega) = S_{CP}(\omega) = \frac{\omega^4}{(\omega_P^2 - \omega^2)^2 + 4\xi_P^2\omega_P^2\omega^2} S_{KT}(\omega) \tag{7}$$

where ω_P and ξ_P are further model parameters, which do not have any physical interpretation and are calibrated to achieve the desiderated high-pass characteristics of the filter. Obviously, other types of high-pass filter can be adopted for this purpose (e.g., Giaralis and Spanos 2009). Figure 3 shows the PSD of the process $y(t)$ obtained adopting the Clough-Penzien (CP) model, using the parameters reported in Table 1 estimated for three earthquakes (Yeh and Wen 1990).

As it has been mentioned, the models described above are unable to reproduce spectral nonstationarity. Limiting to the models based on

linear filtering of Gaussian processes, several approaches to produce spectral nonstationarity have been proposed. These usually adopt linear filters characterized by time-variable parameters that are calibrated to match some feature extracted from natural accelerograms. Several implementations are available, including discrete-time recursive models realized through several parameterizations. Here, a model based on the parametrization of the impulse-respose function IRF of the linear filter as proposed by Rezaeian and Der Kiureghian (2008) is briefly described since it can be easily seen as a generalization of the classical models presented above.

According to this model, the ground acceleration can be expressed as:

$$u(t) = A(t) \left[\frac{1}{\sigma(t)} \int_{-\infty}^t h(t - \tau; \boldsymbol{\theta}(\tau)) w(\tau) d\tau \right] \tag{8}$$

where $w(\tau)$ is a Gaussian white noise with intensity S_0 , $A(t)$ is an envelope function of the type of

Eqs. 3, 4, and 5, $\theta(\tau)$ a vector of time-variable model parameters defining the kernel h , and $\sigma(t)$ is the time-variable standard deviation of the filtered process, which can be obtained as:

$$\sigma(t) = 2\pi S_0 \int_{-\infty}^t h^2(t - \tau; \theta(\tau)) d\tau \quad (9)$$

Stochastic Models for Spatial Variability of the Ground Motion

The seismic ground motion is usually considered as fully correlated in space and it is represented by single-point functions, such as time histories, response spectra, PSDs, or evolutionary spectra. Single-supported structures are usually studied by expressing their equations of motion in terms of relative displacements between the structural elements (or lumped masses) and the ground. In this way, the inertia forces due to the seismic acceleration can be schematized as a system of apparent forces applied on the structural masses and proportional to the acceleration itself. This approach is justifiable for point-like facilities, such as compact buildings, where the lack of correlation of the ground motion may be ignored. However, for spatially extended structures, such as pipelines, or structures based on widely separated supports, such as bridges or viaducts, the partial correlation of the ground motion may be determinant for a reliable structural analysis.

Seismic accelerations recorded at different points of the ground differ because of the loss of coherence that gradually increases with distance and because of the phase shift due to the propagation of the seismic waves (Der Kiureghian 1996). A representation of the seismic acceleration that takes into account its partial correlation may be formulated in terms of multipoint statistics such as the cross-PSD. For multisupported structures, the displacement relative to the ground of the nodal points is not representative because of the variability of the seismic motion. The equations of motion can be conveniently written in terms of absolute displacements, separating the pseudostatic part, due to the static effect of the ground dragging, from the purely dynamic part of

the motion (e.g., Clough and Penzien 1975). The relative importance of these two contributions depends on the stiffness of the structure and on the characteristics of the soil determining the spatial correlation pattern of the ground motion. Many scientific papers investigated this problem concluding that fully correlated motions may produce higher or lower responses than partially correlated motions depending on the dynamic characteristics of structures, on the considered effects and on the cross-correlation between support motions (e.g., Zerva 1991; Loh and Ku 1995; Tubino et al. 2003).

According to Der Kiureghian (1996), four distinct phenomena give rise to the spatial variability of earthquake-induced ground motions: (1) loss of coherency of seismic waves due to scattering in the heterogeneous medium of the ground, as well as due to the differential superpositioning of waves arriving from an extended source, collectively denoted herein as the “incoherence” effect; (2) difference in the arrival times of waves at separate support points of the structure, denoted as the “wave-passage” effect; (3) gradual decay of wave amplitudes with distance due to geometric spreading and energy dissipation in the ground medium, denoted as the “attenuation” effect; and (4) spatially varying local soil profiles influencing the amplitude and frequency content of the ground motion under each foundation point, denoted as the “site-response” effect.

Empirical spectral models have been proposed and validated through array recordings of the ground motion along extended homogeneous areas (Bolt et al. 1982; Harichandran and Vanmarcke 1986; Abrahamson et al. 1991). These models assume implicitly that in each point of the terrain the acceleration can be represented through Eq. 1 as the amplitude modulation of a stationary random process. Accordingly, stochastic models to represent, jointly, the stationary parent process of the ground acceleration in pairs of points of the terrain have been developed. These models can be expressed in the frequency domain through the cross-PSD:

$$S_{y_j y_k}(\omega) = \sqrt{S_{y_j}(\omega) S_{y_k}(\omega)} \gamma_{jk}(\omega) \quad (10)$$

where S_{yj} and S_{yk} are the PSD of the stationary acceleration y_j and y_k in points j and k of the terrain, while γ_{jk} is the coherence function. According to the classification described above, the coherence function can be factorized as

$$\gamma_{jk}(\omega) = \gamma_{jk}^{(\text{inch})}(\omega) \gamma_{jk}^{(\text{wp})}(\omega) \gamma_{jk}^{(\text{att})}(\omega) \quad (11)$$

in which $\gamma^{(\text{inch})}$, $\gamma^{(\text{wp})}$ and $\gamma^{(\text{att})}$ are, respectively, the coherence functions representing the incoherence effect, the wave-passage effect and the attenuation effect encountered by the seismic wave. The site-response effect can be included into the PSD S_{yj} and S_{yk} .

The incoherence effect increases as the distance between the two points increases and is more significant for high-frequency harmonics. Der Kiureghian (1996), on the basis of statistical arguments, concluded that $\gamma^{(\text{inch})}$ can be expressed in the form

$$\gamma_{jk}^{(\text{inch})}(\omega) = \cos [\beta(d_{jk}, \omega)] \exp \left[-\frac{1}{2} \alpha^2(d_{jk}, \omega) \right] \quad (12)$$

where α and β are increasing functions of the distance d_{jk} between the two points, as well as of the frequency. These functions are often assumed as linear functions parametrized by the share-wave velocity.

The wave-passage effect is merely due to the different arrival time of the seismic waves in the two points. The coherence function corresponding to this effect has unitary modulus and can be written in the exponential as

$$\gamma_{jk}^{(\text{wp})}(\omega) = \exp \left[i\omega \frac{d_{jk}^L}{v_{\text{app}}} \right] \quad (13)$$

where d_{jk}^L is the distance between the two points projected along the wave propagation direction and v_{app} is the apparent wave propagation velocity.

The attenuation effect has negligible effects and it may be assumed $\gamma^{(\text{att})} = 1$.

Relationship Between PSD Models and Response Spectrum

For design purpose, the ground motion is usually assigned through acceleration, velocity, or displacement response spectra, while the stochastic representations discussed above are defined in terms of PSD of a parent stationary process and time-modulation functions. The relationship between these two representations is not obvious since it involves the expected maxima of the response of a sdof linear system subjected to the earthquake input, i.e., the response of the system:

$$\ddot{x}(t) + 2\xi_0\omega_0\dot{x}(t) + \omega_0^2x(t) = -u(t) \quad (14)$$

where $x(t)$ is the displacement of the oscillator with respect to the ground, the overdot denotes the time derivative, ω_0 is the natural frequency, and ξ_0 is the damping ratio. The oscillator is at rest when the earthquake arrives at $t = 0$.

Assuming that the input energy is distributed over a broad frequency band, and assuming that the structural damping ξ_0 is low, the response $x(t)$ is a narrow-band process which can be expressed through the Rice representation:

$$x(t) = a(t) \sin(\omega_0 t + \phi(t)) \quad (15)$$

where $a(t)$ and $\phi(t)$ are, respectively, the amplitude and phase modulating processes, whose time scale is assumed to be slow with respect to the carrier wave $\sin(\omega_0 t)$. This assumption reflects the circumstance that the frequency-response function of a linear system with small damping ratios has a very high peak in the neighborhood of $\omega = \omega_0$. Under these hypotheses, the amplitude modulation is a Markov-type random process governed by a first-order stochastic differential equation (Spanos and Solomos 1983) and its time-dependent variance is given by the expression:

$$\sigma_a^2(t) = \frac{\pi}{\omega_0^2} \exp(-2\xi_0\omega_0 t) \int_0^t \exp(2\xi_0\omega_0 \tau) S_u(\omega_0, \tau) d\tau \quad (16)$$

The standard deviation of the response amplitude can be formally related to the displacement response spectrum $S_d(\omega, \xi)$ through the equation:

$$S_d(\omega_0, \xi_0) = g \max_t [\sigma_a(t)] \quad (17)$$

where g is the peak factor (Vanmarcke 1976). Equation 17 establishes a relationship between the response spectrum and the EPSD of the ground motion. This relationship cannot be directly used as the peak factor g is unknown and, in general, depends on the stiffness and damping of the SDOF oscillator, on the frequency content and duration of the input process $u(t)$, and on the level of uncertainty furnished by the design spectrum as specified by codes. The peak factor is often estimated through formulations based on the extreme-value distribution, which, unfortunately, requires substituting the exact response with an equivalent stationary random process having limited duration. The brute-force alternative consisting of computing the peak factor by Monte Carlo simulation (Giaralis and Spanos 2009) seems to be more appropriate.

Closing Remarks

The seismic ground motion can be represented as a random process. Generative models can be formulated on the basis of several principles, including linear filtering and time modulation of a Gaussian white noise. According to this approach, a few classical models of ground acceleration have been described and the basic ideas behind a more recent generalization capable of spectral nonstationarity have been outlined.

When a structure or a facility is extended in space, the model seismic ground motion must reproduce the spatial correlation structure of the phenomenon. A class of spectral models able to represent multiple-point ground motion has been described.

While stochastic models represent the ground motion in terms of EPSD, usual engineering practice uses the concept of response spectrum. A formal link between the two representations is provided and discussed.

Disaster reconstruction stages; Reconstruction expectations

Introduction

Disaster reconstruction has discernible stages which, once understood, can be used to help inform planning and reconstruction. Reconstruction is part of the recovery stage in a disaster and describes the physical regeneration of the built

environment, including housing, commercial buildings, and infrastructure. Disasters are commonly conceptualized in terms of reduction, readiness, response, and recovery stages. Similar to overall disasters, reconstruction passes through a number of stages, during which activities, such as funding, compliance, assessments, and rebuilding, are undertaken. Reconstruction is nonlinear, which means that housing reconstruction might go through reconstruction stages at different times to infrastructure reconstruction and in different locations within the same disaster. Housing, commercial properties, and infrastructure might be temporarily fixed and then permanently reinstated at a later date; however, the overall reconstruction stages are similar for each type of reconstruction. Drawing on previous studies, this article focuses on reconstruction following earthquakes and uses the earthquakes in Canterbury to illustrate the common stages of reconstruction.

The Disaster Reconstruction Process

Reconstruction can be considered in the wider context of an ongoing and fluctuating recovery. Governments have attempted to plan for recovery and to develop policies which incorporate increased resilience into recovery frameworks. An example of these policies can be found in New Zealand where the “Focus on Recovery” (MCDEM 2005), a framework encompassing the community and four environments, social, economic, natural, and built environment, was adopted into the overall civil defense and emergency management framework to provide multilevel and multiagency structures and processes for post-disaster recovery. The reconstruction of the built environment is seen as one of the key elements within recovery. According to Quarantelli (2008) reconstruction refers to the post impact rebuilding of the physical structures destroyed or damaged in a disaster. The relationship between reconstruction and community recovery has been summarized by Quarantelli (2008) as “The longer the reconstruction process, the slower the recovery of the community since recovery in other dimensions is also slowed.”

Reconstruction Following Earthquake Disasters,
Table 1 Wilkinson’s five stages of reconstruction mapped against Brunsdon and Smith’s (2004) reconstruction activities and other key activities

Reconstruction stage	Main activities
Chaos	Impact assessments
Realization	Proposals made
	Interim funding determined
	Governance and organizational structures setup
Mobilization	Reconstruction commences
Struggle	Reconstruction slows as problems emerge
	Problems with compliance, consents, shortages (labor, materials), quality, leadership, housing affordability, conflict
New normal	Establishing new ways of living

By understanding the stages of reconstruction, opportunities can be found for improving and increasing the speed of the overall recovery, including community recovery. The five stages of reconstruction, as discussed by Wilkinson (2013), are identified as chaos, realization, mobilization, struggle, and new normal. Other authors, such as Brunsdon and Smith (2004), listed key activities required for reconstruction as impact assessment, restoration proposal, funding, statutory compliance, and reconstruction. Brunsdon and Smith’s (2004) stages can be integrated into those of Wilkinson’s (2013) to create a fuller picture of the reconstruction process as seen in Table 1.

Reconstruction Stage 1: Chaos

In the initial stages of recovery, there tends to be significant chaos where the general situation is characterized by the question “what do we do?” The key reconstruction features found in this stage are the need for assessments to be done on buildings and communities. Brunsdon and Smith (2004) described the need for impact assessments. These assessment requirements are similar to the World Bank’s recommendations for assessing needs, identifying priorities, and

planning recovery, where one of the first activities usually undertaken is the assessment of damage and the impact of the damage on the community. The World Bank’s Rapid Damage and Loss Assessment (DaLa) methodology provides a way of undertaking the assessment activity, where DaLa incorporates physical damage, losses from that damage, and assessments of social, economic, and environmental impacts. At impact assessment, information is collated on the magnitude of the disaster event on individuals, communities, and the physical environment. The result of the impact assessment becomes the basis for future reconstruction works. Assessments require reviews and updating to take account of new information at later stages. Stakeholders in the reconstruction process are enlisted so that a comprehensive assessment report can be prepared. The success of assessment is greatly enhanced by information gathering, collation, and dissemination approaches, coupled with the level of interaction and planning arrangements that exist between the different disaster stakeholders (Rotimi 2010). Assessment processes are not always well established, so a certain amount of chaos is evident causing confusion and reassessment.

The Canterbury earthquakes can be seen to illustrate this initial chaos stage. Canterbury was significantly damaged by two major earthquakes and thousands of aftershocks. These earthquakes illustrate the five stages of reconstruction. In the first earthquake on the 4th of September 2010, there were no fatalities but widespread damage to housing, infrastructure, and public facilities throughout the city and surrounding areas. After the September earthquake, a large number of unreinforced masonry buildings in the central business district (CBD) were heavily damaged, and large areas of the CBD were cordoned off from the public for approximately 1 week. Engineers were quickly mobilized throughout the country for building damage assessment and safety evaluation. The earthquake produced rapid response and assessment, and structures were quickly put in place to deal with the situation. However, the violent magnitude 6.3 earthquake that devastated Christchurch on

22 February 2011 was the most severe of all the events in the Canterbury earthquake sequence causing the deaths of 185 people, and many buildings were severely damaged including further damage to infrastructure and widespread liquefaction leading to a more complex response, recovery, and reconstruction. The February earthquake also triggered land movement, the collapse of cliffs, and rock falls. As a result of the Canterbury earthquakes, more than 60 % of Christchurch's CBD buildings were severely damaged (CERA 2012). Another 60 % of the 5,000 businesses in the CBD and 50,000 employees were displaced. More than one third of central city businesses were unable to operate, with another third relocating to makeshift premises (DoL 2011). Over 150,000 homes (about three quarters of Christchurch's housing stock) sustained some damage from the earthquakes. The total number of individual buildings, land, and contents insurance claims received in the first year exceeded 600,000 (EQC 2011).

In terms of infrastructure damage, 1,021 km of roading needed rebuilding, which is about 52 % of Christchurch's urban sealed roads. The earthquakes also damaged 51 km of water supply mains and 58 km of the sewer system within the city (CERA 2012).

The initial building assessments for Canterbury earthquake demonstrate the chaos of the initial stages of reconstruction. In the need to act quickly, the assessment methods and protocols were not consistent, and the quality of assessment was variable (NZSEE 2011). The ways in which building assessments were conducted represents the chaos in the initial stages of reconstruction. There were different assessment techniques being used by different agencies, leading to different levels of quality and different information in the assessments. The level of training of the assessment teams varied, leading to the same buildings having different assessment outcomes. Reassessments were commonplace. Inaccurate and incomplete building assessments were used to make decisions, leading to fast-track demolition of buildings.

The chaos stage brings into focus the need to undertake a significant rethink of land use,

involving questions such as: Should we rebuild? Where? Questions about whether to rebuild and where caused uncertainty in the Canterbury earthquakes. Significant land-use reassessment was made to categorize land for rebuilding, but this again was initially characterized by inaccuracies and confusion. Since there was widespread water and waste water system failures, people had to use portable toilets and water tanks delivered water (Potangaroa et al. 2011). Failure to rapidly repair systems and poor quality assessments are typical in the chaos stage.

Reconstruction Stage 2: Realization

Following on from the chaos stage is the realization stage which is characterized by the common thought that "the disaster's impact is bigger than we thought." In this stage, the common elements are around establishing agencies; planning, especially land use and rezoning; new legislation; and the introduction of quickly produced new building codes (which are usually designed to improve past building practices and are aimed at improving resilience). Towards the end of the chaos stage, newly established recovery organizations emerge. For the community at large, there is often ongoing temporary accommodation or temporary displacement and no or minimal rebuilding occurring.

Brunsdon and Smith (2004) discussed the need for decisions on whether to repair, replace, or demolish affected properties and also the need to produce restoration proposals to give an outline of the anticipated reconstruction needs. Proposals outline a range of options for reconstruction, and an attempt to put costs to the reconstruction is often made.

The time period for complete reconstruction is relatively indefinite. It could last months, years, or decades after the disaster event. The sooner good organizational structures, staffed with qualified professionals, are in place, the better for overall recovery. Ensuring a smooth transition from response through relief and recovery is critical to the effectiveness of post-disaster recovery activity (Smart 2012). However, Davies (2006)

points out that "...many [disasters] concern the relentless pressure for rapid recovery from all quarters which is set against the normal demands for prudent planning, detailed consultation, reviews of safety requirements etc. There is also the demand for reform to be balanced with another pressure for realism or a return to pre-disaster norms." The realization stage of reconstruction brings this point into focus, as the debates of what to rebuild, where, and when become more frequent. The Christchurch earthquakes illustrate the structure and tensions of government agencies created to lead recovery and reconstruction. The Canterbury Earthquake Recovery Authority (CERA) was established as a key driver in determining how recovery policy and programs are designed and implemented. CERA as the primary agency for recovery has powers that were stipulated in a newly created Canterbury Earthquake Recovery Act to circumvent existing regulations. The Recovery Act also stipulated the role of the Minister for Canterbury Earthquake Recovery who was appointed by the Prime Minister to coordinate the recovery effort at the executive government level. This minister reports to the Cabinet Committee on Canterbury Earthquake Recovery, which was tasked to oversee and coordinate the government's response to support the recovery and reconstruction. Other government agencies and departments are coordinated through a Senior Officials Group, chaired by the Chief Executive of CERA. Elected members, commissioners, and leaders of the strategic partners are engaged through the Recovery Strategy Advisory Committee (RSAC). The Recovery Strategy, which was released in May 2012, is the overarching document to coordinate actions among CERA, other government agencies, local authorities, and strategic partners (CERA 2012). New Zealand followed Victoria and Queensland's lead in creating a new recovery agency and providing it with enabling legislation (Smart 2012). CERA is equivalent to the Victorian Bushfire Reconstruction and Recovery Authority (VBRRA) established following the bushfires in Victoria and the Queensland Reconstruction Authority (QRA) established following the floods in Queensland. Indeed, Queensland's

institutional response was specifically cited in a New Zealand Cabinet minute proposing the creation of CERA (New Zealand Cabinet Office 2011). Successful post-disaster recovery depends on strong leadership. In Christchurch, the recovery leadership has been undertaken by CERA at the national level. While the establishment of a dedicated response and recovery organization was gaining favor, one critique of this strategy is that the local authorities lost an opportunity to manage recovery and redevelopment of their own city. Tensions often arise at the realization stage, as the leadership and management of disaster recoveries are shuffled between local and central governments.

Another critical decision in relation to the rebuild of Christchurch City Centre was the creation of the Christchurch Central Development Unit (CCDU). The high degree of insurance penetration meant that many commercial building owners have the option of cashing out their buildings and moving their money elsewhere (Taylor et al. 2012). On the other hand, greater certainty of the future is needed to attract capital investment, retain employment, and boost economic development. Within this context, CCDU was established in April 2011 as a central government organization within CERA and tasked with laying out a blueprint for the CBD within 100 days, with the aim of creating confidence in the rebuild of the CBD.

In order to manage a large disaster rebuild, other new structures are often developed. Due to the scale of the February earthquakes, the Stronger Christchurch Infrastructure Rebuild Team (SCIRT) was created to rebuild the horizontal infrastructure (roads, bridges, water systems) and responsible for delivery of all asset assessments, project definition, concept and detailed design, and construction delivery. SCIRT adopted an innovative alliance delivery system for the reconstruction of the horizontal infrastructure. The SCIRT alliance was made up of eight partner organizations, consisting of three client organizations (Christchurch City Council (CCC), CERA, and New Zealand Transport Agency (NZTA)) and five main contractors. Each client plays a different role: CCC and NZTA act as asset

owner and founder, while CERA is mandated to coordinate the overall rebuild activity on behalf of the government. SCIRT is effectively a “virtual organization” which has a leadership team for governance and an Alliance Management Team (AMT) which looks after the Integrated Alliance Team (IAT) who are responsible for delivering the planning, design, and management functions to enable the delivery teams to do the work. The delivery teams are responsible for the construction.

The creation of the Christchurch Central Development Unit (CCDU) was seen as critical for the reconstruction as it created some certainty regarding the plan for new major public buildings and in encouraging investment into the new central city. The release of the Blueprint, the Christchurch Central Recovery Plan at end of July 2011, was regarded as a milestone for the city. The Plan identifies a number of major “anchor” projects that will contribute to recovery. Anchor projects will be progressed by the relevant organizations including CERA and other government agencies and the Christchurch City Council with involvement from the private and philanthropic sectors.

The alliance model adopted by SCIRT is a collaboration between a client, consultant, and contractor who mutually agree to undertake the work to target levels of quality, cost, and time. An additional rewards/sanctions mechanism is put in place to measure the performance of individual delivery contractors over time. Construction work is allocated to them based on their performance. The need to put in more collaborative structures for rebuilding, as demonstrated by SCIRT, has been recognized by Zuo et al. (2006), and the system adopted by SCIRT takes the alliance model concept and applies it in a unique way.

In addition to new structures, the realization stage of reconstruction brings with it decisions of a social, physical, environmental, and political nature which result in conflicts between implementing a speedy recovery and the needs for safety or quality (which reduces initial vulnerabilities) or speed versus wider community participation in decision making. Ingram

et al. (2006) conclude that relief and short-term response can be urgent and rapid; but longer-term recovery needs to be cautiously implemented. Long-term recovery programs have to be based upon comprehensive assessments of risk and vulnerabilities and balanced with overall recovery needs.

At the realization stage, information about the financial impacts of the reconstruction is clearer as reconstruction proposals and the apportioning of funding become key issues. Reconstruction funds may be raised privately, through insurance companies and from external donor agencies or charities. The outcome of funding and other statutory compliance applications may necessitate adjustments to initial restoration plans. Some other factors apart from economic considerations may impact on restoration programs. These may include structural integrity, safety, and functional/historical/cultural significance of the property to the owner. As with many disasters, in the wake of the Christchurch earthquakes, the first source of financial assistance for homeowners was from their own insurance companies. Loss of housing is covered by government-required earthquake insurance, provided by a national Earthquake Commission (EQC). New Zealand administers a disaster insurance scheme that is designed to cover residential property for many geological hazards and residential land for storms and floods. The scheme operates by applying a compulsory levy on insurance policies, the funds from which are pooled into the New Zealand Earthquake Commission (EQC) and used to fund property rebuilding and repair post-disaster.

Under the EQC, the New Zealand Government inherently assumes a degree of responsibility for the risks of events that are destructive but difficult to predict. The availability of insurance and the high level of coverage is a key aspect in financing Christchurch’s earthquake housing reconstruction. The government also shares in the cost of the city’s infrastructure repair. Funding for the infrastructure rebuild is provided through a combination of government subsidies from the New Zealand Transport

Agency (NZTA), CERA, and/or treasury, insurance companies, and council borrowings. The rebuild of the Christchurch central city is largely driven by the Christchurch Central Recovery Plan (CCRP), based around 17 anchor projects to boost business recovery in the CBD. In June 2013, a year after the launch of the CCRP, the central government and Christchurch City Council reached cost-sharing arrangements for the anchor projects in the CCRP and for the repair and replacement of the central city's essential horizontal infrastructure (CERA 2013). It is common at the realization stage to face the realities of the disaster in terms of the financial burden on the community and country, and different financial mechanisms are used to fund recovery.

Hasty reconstruction programs have longer-term impacts that may be difficult to undo (Ingram et al. 2006). Reconstruction decisions should therefore be a trade-off between idealistic goals and expediency. When systems are established, there is a desire to see some action, mainly in the form of rebuilding. Realization leads into the next stage with a need to increase activity; this is the mobilization stage.

Reconstruction Stage 3: Mobilization

Often marking the start of the mobilization stage is the 1 year anniversary of the disaster and the increasing mood to get on with the reconstruction. Mobilization is characterized by the common thought "we're getting on with it." The mobilization stage features high energy and increased decision making. Often public building repairs become evident, especially schools and community centers, as a desire to make physical statements about the rebuilding progress is made. In this stage, the first new buildings emerge, there is high activity in repairs, and an elevated concern about the wider resourcing problems is being encountered, leading to increasing costs and shortages of supply. However, there is much less uncertainty from population in this stage, governance and organization structures for reconstruction are in place, and

increasing activity leads to optimism. At this stage, how the recovery is funded will be a key driver. In Christchurch, because of the very high level coverage, insurance is driving recovery and problems with insurance have become prominent.

Mobilization also brings into focus the needs of housing repairs. Housing is a large component of the disaster recovery in Canterbury. About three quarters of the housing stock in Canterbury sustained some damage from the earthquakes and a mobilized workforce is required to undertake the repairs and rebuilding. Issues concerning insurance payouts have been cited most frequently as a major hurdle to advancing repair and rebuild.

For local residents, the wait for payment from the insurance, combined with the government decision on land zoning, creates additional stress in recovery.

Mobilization is characterized by increased decision making on properties, for instance, in Canterbury, following on from land rezoning, more than 7,800 property owners in the residential red zone were offered a buyout package by the government to leave their uninhabitable houses. The vast majority of red-zone home owners chose the buyout option, selling their property to the government. This residential red zone offer scheme has allowed property owners to move on from the most damaged areas promptly, and the government's assistance has progressed recovery faster than if the usual private insurance process had been left to manage the situation. Other housing decisions describing how the land is expected to perform in future earthquakes prescribed altered foundation. More than 10,000 homes were assessed as requiring substantial foundation work before the houses may be considered safe for living.

Tracking the reconstruction of Christchurch showed that by September 2013, 2½ years after the February 2011 earthquake, demolition of damaged buildings in the CBD was almost complete, and the need for a more tangible sense of momentum and progress through the visible proof of new buildings in the CBD was seen as immediate priorities (NZCID 2013).

Reconstruction Stage 4: Struggle

The increased optimism of mobilization is often followed by a struggle stage. The main mood of the struggle stage is one characterized by the feeling that “it’s really hard, it’s not going to plan.” What appears in this stage is the realization that there will be no fast recovery. Statutory application and documentation procedures have been known to slow down reconstruction programs (Burby et al. 2006). The entire process is worsened by the absence of skilled professionals and skills, such as processing officials, project managers, and essential construction skills. Thus, the period when statutory compliances/consents are pursued is usually characterized by disillusionment of affected individuals and the community. Delays and failures from the new structures and insufficient progress are features of this stage.

Recovery takes a very long time and is always beset with unanticipated problems which slow the recovery timeline. In the struggle stage, there is high activity, such as houses and public and commercial properties rebuilding and businesses returning. New business models emerge as prior models may not cope with the changed business environment. But, at the struggle stage, there are often costs escalating, materials hard to procure, skilled professionals in demand, reduced housing stock, and housing affordability problems. The struggle stage is very hard for the community, and more people start to reassess options, and there are population shifts from the region. In the pursuit of reconstruction objectives, it is usual for conflicts to occur between affected groups, government, and recovery providers. New groups that emerge after a disaster event may have difficulty working together with already established ones (Quarantelli 2008). Auf De Heide (1989) gives three reasons for conflict after a disasters:

- Scarcity of information and/or breakdown in communication among recovery stakeholders
- Challenges posed by the management of limited recovery resources
- Excessive response and recovery provisions by external aid agencies and outsiders

Conflict must be properly managed; otherwise they could have lasting effects on individuals and the community and affect the reconstruction. Picou et al.’s (2004) study suggests that the scale of litigations among stakeholders during reconstruction programs could become very extensive because of disaffection with the recovery process (and when recovery needs are unmet).

The reconstruction process involves the application for resource consents and building approvals. Consenting processes are usually painstaking for both the party(s) seeking approvals and the approving authorities. Approving authorities need to ensure that performance quality and safety provisions are not compromised. It is necessary to ensure that a considerable level of resilience is incorporated in all post-disaster development proposals.

Three years after the February 2011 earthquake, the pace of physical rebuild can be seen to represent the struggle stage, where reconstruction progress is gradual. In spite of the various stakeholders involved and different funding mechanisms and organizational structures applied in the rebuild sectors, other issues have emerged which have started to represent a struggle for the region’s reconstruction.

For instance, the Canterbury earthquakes exposed the lack of construction-related professionals for the rebuild. Demand for skills, such as demolition, repairs and construction, and associated professional services, has increased considerably in Canterbury since February 2011 (Chang-Richards et al. 2013). There have been difficulties in recruiting workers with desired skills. Resource pressures on rebuild projects remain primarily from human resources associated with structural, architectural, and land issues relating to rebuilding. Resource shortfalls have had an inflationary impact. The inflationary effects of increased construction professional fees and an increase in temporary house rentals for the inbound construction workforce have become major concerns.

Some engineering consultancies have reported ongoing issues sourcing people with high skill levels. Young engineers and mature project

management skills from Europe continue to be the largest inbound demographic group involved with the rebuild. Some construction organizations faced difficulties with immigration issues and housing their incoming workforces. At the same time, the inflationary impact which flowed through to higher property rents made attracting tradespeople from other parts of New Zealand more difficult.

According to official projections, there will be an additional 17,000 workers needed to meet demand at the height of the rebuilding activity in late 2014. Flowing on from the rebuild, another 15,000 workers will be needed in supporting roles and sectors, including such as administration, law, accounting, retail, accommodation, and services (MBIE 2013).

Given that the habitable housing stock has been greatly reduced in the earthquakes, Christchurch City has found it difficult to ensure the market provides enough affordable housing for displaced residents. Compounding this shortage was the need to house a large number of additional rebuild workers. A lack of temporary accommodation has been an ongoing concern which constrains labor supply.

The government created three temporary villages and developed about 40 permanent units to fill the gap of unmet housing needs for displaced residents. Housing New Zealand has initiated a progressive approach to rebuilding quake-damaged social housing properties in the eastern suburbs.

A survey undertaken by the Tenants Protection Association (2013) in June 2013 investigated the effects of rising rents on tenants. Of 365 surveyed tenants, 85 % reported to be negatively affected by rent increases. 60 % reported paying over 40 % of their annual income in rent. The average rent increase was \$43 dollars per week. Some areas such as “Inner North” and “North West” Christchurch recorded above-average rent increases of 39 % and 32 % respectively (MBIE 2013).

An estimated minimum of 10,000 homeowners and occupants will have to relocate to temporary accommodation while further repairs are carried out. As the rebuild proceeds,

construction-related inflation as a result of this rent inflation is likely to put extra pressure on the Canterbury labor market, community recovery, and regional economic development. The shortage of accommodation also appears to be a constraint on the rate at which the labor force is brought into the region.

One of the consequences of the sheer damage to housing is that there are thousands of buildings that need remedial work or rebuild for which a building consent will be required. This has led to the Christchurch City Council Building Consent Authority being overwhelmed by the volumes of building consents with criticism around the council’s inability to meet statutory timeframes for processing building consents.

Christchurch applicants had been expressing a significant level of concern over the time needed for consent. Given the projected rebuild activity for the coming years, the central government had to intervene to aid Christchurch City Council in changing its building consent functions with a more streamlined process around commercial and residential building consents.

There was also a lack of consistency of work procedures, difficulty in meeting requirements in terms of quality of work, and a lack of people to do the work. There was also a need for the construction industry to respond, plan, and train for the new/improved requirements of the rebuild.

The process from earthquake impact to longer-term reconstruction is complicated by a lack of prior capacity and experience in both local authorities and the insurance industry to deal with multiple events of large scale. The first 2 years’ reconstruction process was rife with uncertainties about land decisions, timeline of insurance payouts and housing repairs, as well as the eventual cost for the rebuild.

The rebuild has been slow because of the ongoing aftershocks, scale of the disaster, delays in resolving multi-event insurance claims, and skills shortages. Canterbury is still very much in the struggle stage of reconstruction, and this will continue for many years, as the new buildings, anchor projects, and housing are gradually rebuilt. The new normal stage follows the struggle stage.

Reconstruction Stage 5: New Normal

The new normal stage, which starts many years after the disaster, is characterized by the feeling that “this is how it is, there’s no going back.” There is always a new normal stage following a disaster. This stage finds landscapes now looking very different. Disaster recovery and reconstruction do not recreate the same environments seen prior to the disaster. Everything is different; the way people conduct business has changed; building work is still ongoing, but the architecture is different, and there are often delays; community configurations are different; and community and social facilities are relocated and often reconfigured. However, this new normal stage is a time where the community starts accepting the new normal environment. Where resilience has been introduced into the buildings and community, there is a sense of buildings being better, newer, and safer. The community starts living differently from prior to the disaster. For Canterbury, currently in the struggle stage of the recovery, there is hope for the future as the new normal stage comes closer.

Schneider (1992) suggests that stakeholder conflicts may also result from the emergence of new social norms after a disaster event which may not mesh well with traditional norms. From an individual or group perspective, stakeholders then struggle to reestablish or maintain their previously recognized roles, responsibilities, and boundaries. Chief among post-disaster management objectives is to enable a community to recover from the event while also future-proofing the community and its physical facilities against similar disaster events. New normal brings this debate into focus, where people feel that they are more likely to be prepared for any future disasters and that their facilities are better able to cope.

Summary

Development of the five stages of reconstruction (initial chaos, realization, mobilization, struggle, and new normal) through the lens of a recent

earthquake demonstrates the difficulty of disaster reconstruction. However, understanding the discernible stages can help inform the planning and reconstruction of subsequent disasters. The experience of the Christchurch rebuild has confirmed much of what is known about post-disaster recovery, including the importance of leadership, funding availability, participation of local communities, and timing of decisions. Reconstruction is a complex and dynamic process, full of uncertainties and stress, requiring a significant level of coordination and innovation. Reconstruction of housing, infrastructure, and commercial buildings requires an understanding of the stages, and how recovering cities move from one stage to another, and the elements requiring consideration on the reconstruction timeline. Although disaster reconstruction moves at different speeds, depending on the differing circumstances of the affected area, the reconstruction stages remain relatively static.

Reconstruction in Indonesia Post-2004 Tsunami: Lessons Learnt

Teddy Boen

PT Teddy Boen Konsultan, Jakarta, Indonesia

Build back better; Leadership; Post-disaster recovery

Introduction

On December 26, 2004, a powerful earthquake of magnitude 9.2 occurred in the Indian Ocean,

approximately 150 km off the west coast of Meulaboh, Sumatra Island, Indonesia. The resulting tsunami affected several countries around the Indian Ocean, with Indonesia suffering the greatest. In Aceh, the northern province of Sumatra, 131,000 were confirmed dead and 37,000 missing and approximately 500,000 internally displaced people (IDP) (Iwan, 2006). The tsunami caused a massive damage to housing and infrastructure, and the disaster significantly impacted the social fabric and government administration of the affected communities.

To ensure a speedy, effective rehabilitation and reconstruction of Aceh and Nias, on April 16, 2005, the government established the Rehabilitation and Reconstruction Agency (BRR, Badan Rehabilitasi dan Rekonstruksi NAD-Nias). BRR was an agency with the authority to plan, implement, control, and evaluate the process of rehabilitation and reconstruction. BRR's term of operation was 4 years and was based in Banda Aceh with a branch office in Nias and a representative office in Jakarta. BRR reported the progress of activities directly to the President of the Republic of Indonesia. The main mission was to restore livelihoods and strengthen communities in Aceh and Nias by designing, monitoring, and coordinating community-based reconstruction and development programs.

The December 26, 2004, tsunami that caused extensive damage in Aceh created an opportunity for mitigation, particularly with large sums of money available for rebuilding due to domestic appropriations and international relief. Opportunities arise to intervene in the course of earthquake. A large proportion of the fund was utilized for the reconstruction of approximately 127,400 houses, and unfortunately most of the houses built are not seismic resistant. The February 20, 2008, Simeulue earthquake demonstrated the weaknesses of the houses built; many were heavily damaged or collapsed, even while being constructed. Poorly built houses indicate that the mitigation opportunities to create an earthquake-resistant community were not implemented. The cause for ignoring mitigation opportunities could be lack of knowledge regarding disaster risk management and

the heavy dependency on external resources (financial and "experts") causing the loss of local control.

Having observed the rehabilitation and reconstruction of the houses in Aceh and Simeulue for almost 6 years, the author tries to summarize those shortcomings so that it can serve as lessons learned to other reconstruction projects all around the world, particularly in developing countries.

Below is a summary of reconstruction issues that were brought forward by the author and reconfirmed by others that resulted in poorly built houses in Aceh:

Needs Assessment and Site-Specific Information

A detailed and accurate disaster assessment is a very important factor for a successful planning and execution of the rehabilitation and reconstruction. Such assessment is expected to produce reliable data of beneficiaries of houses. The reliable data is vital prior to commencing the actual reconstruction (Boen 2008). However, in Aceh, there was limited awareness of the need for surveys and lack of expertise to specify or carry these out. The adequate surveys were not systematically completed (Ove Arup & Partners Ltd. 2010).

One of the major flaws was the poorly prepared beneficiary lists, which in turn caused many other problems; among others, the number of IDP and housing needs is constantly changing depending on the various sources. Beneficiary identification and verification was prone to corruption, for example, selling of family ID cards to outsiders by the head of the village, playing off one agency against another, or including relatives returned from other areas of Indonesia to receive multiple houses (IRIN Humanitarian News and Analysis 2009; Ove Arup & Partners Ltd. 2010). Besides that, many foreign "experts" introduced all sorts of house types which are not the prevailing practice, and many are culturally unacceptable. As the result of incorrect needs, to date many houses built during the reconstruction and rehabilitation period are still unoccupied or become wild occupations, and many already deteriorated.

The poor quality of houses was also a result of lack of assessment concerning the real need of materials, construction workers, and technical supervisors.

Directives From the Authority

Any successful reconstruction needs a capable authority with strong leadership that can provide clear directives and requirements concerning the type of buildings and the standards to be followed from the onset. Capable means professionals are familiar with construction of buildings as well as infrastructures and are knowledgeable about the disaster being dealt with.

The approval/permit system must be strictly enforced, and continuous qualified technical assistance and inspection need to be provided.

In Aceh, most nongovernmental organizations (NGOs) felt that BRR did not provide clear-cut guidance, particularly with regard to quality of the construction (Boen 2008; Ove Arup & Partners Ltd. 2010). In July 2005, BRR published the Building Code of the Province of Nanggroe Aceh Darussalam, which provided detailed technical requirements for houses. However, in this building code, there was no guidance on seismic resilient design, and this building code made no reference to national or international standards which were confusing for the donors/NGOs. Therefore, NGOs developed their own guidance. Unfortunately, the guidance in some cases provided incorrect or conflicting details. Several NGOs complied with the Building Code for Aceh assuming that it was sufficient and that local designers and contractors knew what they were doing without realizing that safe construction practices were not common practice. Multiple guidelines caused confusion as to what was deemed appropriate, rather than providing clarity as to which codes and standards should apply (Boen 2008; Ove Arup & Partners Ltd. 2010).

Relevant guidance for good practice of non-engineered buildings for new construction existed or had been developed for Indonesia, long before the reconstruction in Aceh and Nias,

since 1978 (Boen 1969, 1978; Arya et al. 1980; Ove Arup & Partners Ltd. 2010). However, lack of coordination, knowledge, and leadership within the shelter sector resulted in that these good references were not widely distributed and were frequently either not known about (Ove Arup & Partners Ltd. 2006, 2007). All those relevant materials were ignored, and instead, many foreign consultants made their own layout and adopted the confined masonry construction method, but leaving out the detailing for seismic resilience (Ove Arup & Partners Ltd. 2006, 2007; Boen 2008; Ove Arup & Partners Ltd. 2010).

From surveys in Aceh and Nias, almost all designers did not follow the existing guidelines and did not perform the necessary appropriate analysis and design for earthquake resistance (Ove Arup & Partners Ltd. 2006; Boen, 2008b, c; Ove Arup & Partners Ltd. 2010).

Differentiation Between Emergency Shelters and Transition and Permanent Houses

Reconstruction of houses after a disaster must be planned within the overall context of phases from emergency shelter to durable solutions. Differentiation between emergency shelters, transition houses, and permanent houses shall be made.

In Aceh, shelter policy was not developed within the overall context of the journey from emergency shelter to durable solutions, and over the first 6 months, there were considerable confusion and no clear policy as to the type of shelter assistance required (Ove Arup & Partners Ltd. 2010). In the early stage, many of the houses already built were of the transition type but built on permanent former lands belonging to recipients. Many of those “temporary/transition” houses become permanent, and the final reconstruction stage failed to materialize (Boen 2005; Ove Arup & Partners Ltd. 2007).

The need for “permanent” housing in part reflected the large amount of funding available and was articulated in terms of reconstruction rather than the recovery. This led to a focus on physical construction rather than how the process

of rebuilding can lead to economic activity and the role that shelter plays in meeting needs and allowing families to return home and carry out their livelihoods.

Influx of Local and Foreign “Experts”

In Aceh, although numerous contracting firms established themselves after the tsunami, there was no process of certification to guarantee their competency. Out of over 200 NGOs engaged in reconstruction, most had no previous experience in the trade of earthquake-resistant houses construction, and some of them had to terminate agreements mid-contract due to poor workmanship or faced expensive remedial works (Boen 2008; Ove Arup & Partners Ltd. 2010). The lack of immediately available site-specific information was coupled with the influx of many so-called experts (local and foreign) offering an endless number of earthquake-resistant building type “solutions” causing unsatisfactory results. Many NGOs ended in trying to “reinvent the wheel” by introducing house types defying the local culture. Only few NGOs constructed houses based on the prevailing culture in Aceh (Boen 2005; Ove Arup & Partners Ltd. 2007; Boen 2008).

Another major drawback was the fact that NGOs, world organizations, donors (countries), Red Cross, and Red Crescent did not have the necessary experience as well as expertise in post-disaster reconstruction of houses combined with lack of strong leadership from the BRR side in providing guidance as well as data for the post-disaster reconstruction. Some of them had experience in emergency response, and therefore, those “experts” lacked technical capacity and a clear understanding of the local building culture and the social order of the community as well as the ability to adapt disaster-resistant techniques to local styles and situations. Many of them had never previously worked in a post-disaster situation, particularly in reconstruction, and had not worked in Aceh before. They were often unaware of the specific objectives to reduce vulnerability and initially considered seismic resilience as an

optional rather than an essential requirement (Boen 2008; Ove Arup & Partners Ltd. 2010).

Even though Indonesia is highly vulnerable to earthquakes, seismic engineering does not form a core topic in undergraduate engineering degree programs leading to Bachelor of Engineering (Civil). During the reconstruction of Aceh, many of them had only recently graduated and had no practical experience or knowledge of seismic design and to specify and verify materials. Therefore, they failed to anticipate or spot problems and needed training and supervision. The knowledge of local engineering consultants could not be assumed to include seismic design particularly for earthquake-resistant design of houses (Boen 2008; Ove Arup & Partners Ltd. 2010). This was in spite of the fact that relevant guidance for good practice of non-engineered buildings for new construction existed or had been developed for Indonesia since 1978 (Boen 1969, 1978; Arya et al. 1980; Ove Arup & Partners Ltd. 2010).

Designs of Houses Are Culturally Inappropriate and Not Sustainable

The majority of the buildings, particularly houses that were destroyed by the tsunami in Banda Aceh City and villages in Lhoknga and Krueng Raya and Meulaboh City and villages along the west coast of Aceh, such as Calang, were non-engineered buildings consisting of two types: the first type was a one or two stories confined masonry buildings which were earthquake resistant if built with good quality materials and good workmanship and the second type was timber construction (Boen 2005).

However, as the economic condition is prospering, people tend to upgrade their timber houses into masonry because a measure of status is associated with the owners of such masonry houses. Therefore, for the reconstruction program, confined masonry houses shall be constructed as permanent houses because they are in accord with the local culture and will therefore be sustainable (Boen 2006a). In most cases, the quality and strength of masonry buildings

must be improved; however, it would be wrong if instead of enhancing the trade, they try to reinvent the wheel by introducing “alien” types of houses (Boen 2005).

Many NGOs introduced alien construction methodologies that will not be sustainable apart from being seismic resistant (Boen 2006a, 2008c). They did not realize that reemergence of alien construction methodologies was not preferred by the Indonesian people and culturally inappropriate. Some of the alien methodologies observed by the author in the second and fourth quarter of 2007 were precast construction, interlocking masonry, and light-steel construction (Boen 2008c; Ove Arup & Partners Ltd. 2010).

The trouble with these “alien” types of houses is that the buildings last as long as the fund is still available. As soon as the fund is stopped, the village people cannot employ the skills they have learned because they cannot afford the materials (Boen 2008b).

No Standard Construction Drawings nor Building Specification

Most agencies jumped to developing design solutions without attempting to comprehensively define quality or develop a brief or building specification. There was no shared understanding among communities, BRR, and the NGOs as to what quality comprised.

Many designs were developed without engineering input. Standard good practice such as the incorporation of ring beams, ties, and adequate laps between reinforcement was not shown on construction drawings, and specifications did not adequately cover material quality, testing, and workmanship. The facilitators and consultants hired were civil engineers and architects with no specific seismic experience and were unaware of the importance of ductile detailing. The design did not account for seismic loads, and the construction drawings prepared were inadequate, not highlighting the importance of ductile detailing (Boen 2008b, c; Ove Arup & Partners Ltd. 2010).

All NGOs were under pressure to build quickly to meet donor timescales and beneficiary expectations. Most of the time, this resulted in the use of substandard materials, especially poor-quality bricks. Brick quality was typically left unspecified, and the strength of bricks was not qualitatively tested on delivery. The quality of the bricks used in many housing constructions were in general below standard. The sizes were not uniform; it could be easily snapped in half or crushed underfoot, and some even “melted” if exposed to rain (Boen 2006a; Ove Arup & Partners Ltd. 2010).

The quality of the mortar for the masonry walls were also not well controlled, and the proportions of the mortar mixes were also not known and were left at the discretion of the foreman and the construction workers. In some places, the quality of mortar sand was good (the mud content is low), but in most cases the mud content was a bit high.

Main Target Is Numbers and Not Quality

Through the papers that the author published regarding the reconstruction of houses in Aceh, the author suggested to go beyond numbers for the reconstruction of houses and to concentrate on the technical as well as quality of the houses (Boen 2006a). However, until BRR was dismissed (April 2009), the main target was still numbers and not quality (Boen 2006a, b; Nazara and Resosudarmo 2007; Boen 2008c; Ove Arup & Partners Ltd. 2010). BRR still emphasized on providing houses rather than assistance to reconstruct. The focus was on physical construction rather than responding to the way that the process of rebuilding can lead to economic activity or the role that shelter plays in meeting needs and allowing families to return home and carry out their livelihoods (Ove Arup & Partners Ltd. 2010).

BRR claimed that the reconstruction of houses in Aceh and Nias was the fastest in the world (Multi Donor Fund for Aceh & Nias 2007). Some NGOs also claimed that reconstruction and rehabilitation of Aceh and Nias was

successful and could be instrumental for effective disaster response, both as immediate and longer-term strategies in future post-disaster responses in Indonesia and around the world (Multi Donor Fund for Aceh and Nias 2009). However, BRR and NGOs did not prioritize the quality of the built houses and missed the opportunity to “do it right the first time” with the aim to prevent vulnerabilities in future earthquakes. Most of the houses built so far were not earthquake resistant and need to be retrofitted (Boen 2005, 2006a; Ove Arup & Partners Ltd. 2006; Boen 2006a; Ove Arup & Partners Ltd. 2007; Boen 2008a).

Site Development and Infrastructure

The planning of site engineering design and infrastructure must run parallel to the planning of the site layout (Boen 2006a) and must be constructed during the site preparation stage. However, in Aceh, the engineering design still was left out (Boen 2008b; Ove Arup & Partners Ltd. 2010). The drainage, sanitary facilities, and water supply facilities were not constructed parallel with the construction of the housing complexes.

BRR negotiated agreements with the electricity and water boards to provide free connection to the houses built after the tsunami, but responsibility for notifying the electricity and water boards where connections were required was not clear. Many NGOs expected this to be done by BRR and they themselves tended only to make a recommendation to connect once the houses were completed. Consequently, supplies were seldom in place when the houses were first occupied. This resulted in many houses remaining unoccupied (Ove Arup & Partners Ltd. 2010).

Misinterpretation of Community-Based Reconstruction

Local communities will need to be actively involved in planning, decision-making, and implementation in most sectors if reconstruction is to be successful. At the onset of the reconstruction of houses in Aceh and Nias, one of

BRR’s missions was community-driven or community-based reconstruction. Community-based construction is a bottom-up model; beneficiaries are involved, jointly with the professionals, in planning and implementation (Boen 2008b; Boen 2008c). They are engaged in decisions about the project through discussions among themselves and professionals. Participation stimulates self-reliance, because people who participated in their own house building will be confident about problems and less dependent on outside agencies.

However, in Aceh, not all will contribute, and, in most communities, the collaboration with professionals will be largely left in the hands of representatives or local leaders. At the beginning of reconstruction of houses in Aceh, most of NGOs and other organizations provided the fund but left the purchasing of materials and hiring of construction workers to the beneficiaries. They forgot that with community-based mass housing, the quality control becomes a difficult issue. In the course of the reconstruction, due to many complications and misinterpretation of community-based construction, BRR, NGOs, and other donors moved to project type of construction by assigning a local contractor to do the job, and the beneficiaries were not involved in the construction of the houses.

Core Housing, Building Completion, and Further Extension

Core houses are frequently introduced but seldom really understood. Many architects working for NGOs as well as world organizations were suggesting that the 36 m² house should be considered as a core house that can be extended by the beneficiaries at a later date. Such opinion became very common in Aceh and Nias, while in fact, in earthquake-prone countries like Indonesia, it is not advisable to encourage beneficiaries to extend their houses unless the extension is predesigned and all the connections for the extension are already in place.

The extension and original core house must be united structurally to act as one integral unit when

shaken by earthquakes. The newly extended house must be reanalyzed because the new extended house will behave differently than the original core house. Or the extension house shall be structurally completely separated from the core house.

Summary

To prevent similar mistakes as in the reconstruction of Aceh, it is high time to produce a clear guideline for governments:

- Governments must develop and implement a solid strategy for the reconstruction or possible retrofit of the nation's buildings and infrastructure.
- Governments must appoint a professional to head the reconstruction with strong leadership qualification and not merely a political figure and must have track record in disaster mitigation.
- Government must allocate resources, tasks, and time to guarantee continuity in organizational structures and procedures across changing budget years, personnel assignments, and administrative regions.
- Governments should identify and utilize existing resources (including labor, expertise, materials, and funding) available within the country.
- Governments must organize themselves appropriately in order to screen intelligently resources and skills as they are offered and at the same time to resist/reject unneeded or unwanted supplies, personnel, experts, and advice.
- Governments should screen where support from other countries and organizations will be necessary.
- Donors and world organizations should avoid offering unneeded and unwanted supplies, personnel, advice, and particularly "experts" and avoid being arrogant by assuming that the disaster-stricken countries in the developing world cannot take care of themselves.

common way of recording the signal nowadays is digitally. The signals from the sensor can be very small, in the order of microvolts, and cannot be used directly. The signals can also include undesired frequency content so before recoding the signal, it may have to be amplified and possibly filtered. In addition, the signals must be time stamped.

A recorder and a sensor is called a seismograph and consists in most cases of separate units. The reason for the separation is that the sensitive seismometer has to be placed at the most low noise site possible, with little disturbance from the recorder and people operating it. For field use, the ease of deployment makes it desirable to have one compact unit; in particular strong motion instruments – less sensitive – are often sold as complete units with sensor and recorder integrated.

The different steps needed in the process of recording seismic signals will be described.

Recording Seismic Signals

Accelerometer; Digitizer; GPS timing; Recorder; Seismometer; Transmission of signals

Introduction

Seismic signals are detected by seismic sensors that can be seismometers, detecting ground velocity, or accelerometers, detecting ground acceleration. The sensors give out an electrical signal proportional to the ground motion. In order to use the signals for analyzing the ground motion, they must be recorded. A recording on paper is called a seismogram; however, the most

Analog Recording

Recording in analog form on paper continues to some degree despite the advance of digital technology (see Lee and Stewart 1981, for more details). Very few, if any, analog recorders are sold today, but there are probably hundreds still in operation. An analog recorder provides a simple, very reliable real-time backup recording. They are also popular for public relations. Thus, some observatories continue to have a few stations recording on analog recorders. A brief description of analog recorder will therefore be included here.

All analog paper recorders are based on a rotating drum with a pen which moves along an axis parallel to the rotating axis to provide a continuous trace for the whole recording period, usually 24 h. Old photographic recorders usually moved the drum itself along its rotating axis. For this reason, these recorders are often called helical drum recorder or helicorders. A block diagram of a complete system is represented in Fig. 1.

Recording Seismic Signals, Fig. 1

A complete analog recorder. The time mark generator is an accurate real-time clock which might be synchronized with an external time reference. GPS stands for Global Positioning System (Figure from Havskov and Alguacil 2010)

Recording Seismic Signals, Fig. 2 An example of an analog recording from a seismic recorder. The figure shows part of a seismogram. The time marks are 60 s apart

The time marks (Fig. 2) are usually generated at each minute, hour, and 24 h and have different lengths. The time mark generator can usually be synchronized with an external time reference.

The earlier recorders were recording on photographic paper, like the famous *World Wide Standard Seismographic Network* (WWSSN) system (for details, see Willmore 1979), while all recorders now record with either ink or a thermal pen on heat-sensitive paper. Figure 2 shows an example of a recording and Fig. 3 shows an example of a drum recorder with a seismogram.

Apart from not recording digitally, the big drawback with the analog recording is its low dynamic range. The maximum amplitude is usually 100 mm and the minimum discernible

amplitude is about 0.5 mm, so the dynamic range is 200 or 46 dB. This can be compared to digital recorders, which achieve up to 150 dB dynamic range. This corresponds to an amplitude of 15 km on the paper recorder!

It should be noted that with digital recording it is of course possible to create a similar “paper” seismogram from the recorded signals and this is a quite common practice, although the seismogram rarely is printed but available on screen; see Fig. 4

Digitization

A requirement for recording the data digitally is to convert the signal from analog to digital form.

Recording Seismic Signals, Fig. 3 An example of a drum recorder. The unit consists of a rotating drum with paper and a pen mounted on a pen motor (*above* plot, not seen) that translates from left to right as the drum rotates. The gain of the pen amplifier is variable to

adjust to different noise conditions. The seismogram shows the increase in earthquake activity during a dome-building eruption of Mount St. Helens (From vulcan.wr.usgs.gov/Images/Gif/Monitoring/Seismic/seis_garden.gif)

Recording Seismic Signals, Fig. 4 A 24-h seismogram produced from a digital recorded signal. This is a recording of the 17 January 1994 Northridge earthquake

(M6.7) near Los Angeles at 1230 GMT (Figure from topex.ucsd.edu/es10/lectures/lecture11/lecture11.html)

Recording Seismic Signals, Fig. 5

The analog-to-digital conversion process. The arrows show the location and values (amplitudes) of the samples, and the signal is thus approximated with a sequence of numbers available at time intervals Δt (Figure from Havskov and Alguacil 2010)

The process of converting a continuous analog signal to a series of numbers representing the signal at discrete intervals is called analog-to-digital conversion and is performed with analog-to-digital converters (ADC). Figure 5 shows a signal, where the amplitude is sampled at regular intervals Δt .

The process of analog-to-digital conversion involves two steps: first, the signal is sampled at discrete time intervals, and then each sample is evaluated in terms of a number which then corresponds to the amplitude at the time of sampling.

An ADC will give an output binary number when a specific voltage is input. In a computer, numbers are usually represented by a 2-byte word or 4-byte word (1 byte = 8 bits); hence there are 2^{16} or 2^{32} possible values. Since numbers are positive and negative, the corresponding ranges are $\pm 2^{15}$ and $\pm 2^{31}$, respectively (more exactly, $+2^{15}$ to $-2^{15} + 1$ or $+2^{31}$ to $-2^{31} + 1$, because the 0 value has to be included in the 2^n possible codes and the so-called two's complement code is used).

The best ADCs sold for seismology can resolve a step of $0.1 \mu\text{V}$ and has a range of $\pm 2^{24}$ although the most common maximum is $\pm 2^{23}$ (approximately $\pm 8 \times 10^6$). A converter resolving $\pm 2^{23}$ is called a 24-bit converter, and similarly a converter resolving $\pm 2^{15}$ is called a 16-bit converter.

The digitization process will introduce errors into the data and limit the information in them,

simply because a continuously varying signal is replaced by with a discrete set of points. Each sample point is converted from analog to digital form. Since only discrete amplitude values are available, there will be an error, the so-called quantization error. Also there is no information about the signal level between samples in time. This creates errors in both the amplitude and frequency content, and much of the efforts in improving the ADC process are related to minimizing these errors. Before getting into that discussion, it is illustrative to describe how a common ADC works in principle. For a mathematical theory of sampling, A/D conversion process, and other general aspects of seismic recorders, see Asch (2012).

A Typical ADC: The Ramp ADC

One of the simplest approaches of implementing an ADC is the ramp ADC. Figure 6 shows a simplified diagram. The control logic sends a signal to the ramp generator to start a conversion. The ramp generator then generates a ramp signal starting from level 0 (seen on left). The ramp signal enters the comparator, and once the ramp signal is larger than or equal to the input signal, the output from the comparator switches from zero to 1. At the same time as the ramp generator starts, the counter will start to count the number of levels on the ramp. When the comparator switches to level 1, the control logic will stop the counter and the number reached by the

Recording Seismic Signals, Fig. 6 Ramp ADC, see text (Figure from Havskov and Alguacil 2010)

counter is then a measure of the input voltage. After some time, the counter is reset and a new sample can be taken.

The ramp ADC is relatively slow and even slower if a high resolution is required. It also becomes slower as the number increase in size since the counter has to count longer for large amplitudes. An improvement of the ramp ADC is the successive approximation ADC, which is almost identical to the ramp ADC except that it has a more sophisticated control circuit. The converter does not test all levels, but first tests if the input level is below or above half the full scale, thus the possible range has been halved. It then tests if the input level is above or below the middle of this new range. The conversion time is much smaller than for the ramp ADC and constant. This design is the most popular of the classical type of ADCs. A typical 16-bit digitizer of this type may have a conversion time of 20 μ s, which is fast enough for multichannel seismic data acquisition.

Multichannel ADC

There is usually more than one channel to digitize. For three-component stations, there are 3, while for telemetric networks or small arrays,

there might be up to 100 channels. The simplest approach is to have one ADC for each channel. There are several ADC converters that have up to 64 channels with 16-bit resolution and sampling rates in the kHz range. These units only have one ADC. The ADC has, in the front, a so-called multiplexer which connects the ADC to the next analog channel as soon as a conversion is finished. The input signals are therefore not sampled at the same time, and there is a time shift, called skew, between the channels. If the ADC is fast, the skew might be very small, but in the worst case, the ADC just has time to take all the samples, and the skew is the sample interval divided by the number of channels. For many applications, like digitizing the signal from a network, skew has no importance, but in other applications where a correlation between the traces will be made like for arrays or three-component stations, the samples should be taken at the same time. The standard in seismic recorders now is to use one ADC per channel.

Some Basic ADC Properties

Resolution. The smallest step that can be detected which is the input voltage change corresponding to one count, i.e., a change of the *least significant*

bit (LSB, the rightmost bit). For a high dynamic range digitizer, this could be 0.1–1 μV . The number of bits is also often referred to as resolution. Most ADCs have an internal noise higher than one count: in this case, the *number of noise-free bits, rather than the total bit number, limits the effective resolution*. For instance, one count corresponds to 0.3 μV in a 24-bit ADC with a full scale of $\pm 2.5\text{ V}$, but it may have a noise of 2 μV peak to peak, and signals under this level cannot be resolved in practice.

Gain. The sensitivity expressed in counts/V. It can be derived from resolution. If, e.g., the resolution is 10 μV , the gain would be 1 count/ $(10^{-5}\text{ V}) = 10^5$ counts/V.

Sample rate. Number of samples acquired per second. For seismology, the usual rates are in the range 1–200 Hz, while for exploration seismology, sample rates can be more than 1,000 Hz. In general, the dynamic range of the ADC degrades with increasing sample rate, since its internal noise increases with bandwidth.

Dynamic range. Defined as the ratio between the largest and smallest value the ADC can give. For some digitizers, the lowest bits only contain noise, so the dynamic range is defined as the ratio between the largest input voltage and the noise level of the digitizer. This number can be substantially smaller than the theoretical largest dynamic range of a digitizer and may depend on the sampling frequency. So, to give one number for the dynamic range, a frequency bandwidth should ideally also be given. It is normally expressed in decibels (dB): every 20 dB means a factor 10, e.g., 120 dB is a dynamic range of $10^6:1$.

Dynamic range in terms of bits. The dynamic range can also be given as number of bits available in the output data sample. An n -bit converter then gives the numbers $0 - 2^n$ or in bipolar mode $\pm 2^{n-1}$. 12-, 16-, and 24-bit converters are the most used, with 24-bit converters dominating the market. 24-bit converters give out 3 bytes, while 25-bit converters use 4 bytes for storage.

Noise level. Number of counts out if the input is zero (subtracting DC offset). Ideally, an ADC should give out 0 counts if the input is zero. This is usually the case for low dynamic range digitizers 12–14 bits, but rarely the case for high

dynamic range digitizers. The noise level is most often given as an average in terms of RMS noise measured over many samples. A good 24-bit digitizer typically has an RMS noise level of 1–2 counts.

Cross talk. If several channels are available in the same digitizer, a signal recorded with one channel might be seen in another channel. Ideally, this should not happen, but it is always present (maybe at very low level) in practice. The specification is given in dB meaning how much lower the level is in the neighboring channel.

Nonlinearity. If the analog input is a linear ramp, the nonlinearity is the relative deviation of the converter output from the ideal value. It is expressed with relation to full scale (FS), e.g., 0.01 % of FS. For high dynamic range converters, it is important because a poor linearity may cause two different signals at the input to be intermodulated (the amplitude of one depends on the other) at the output. Usually, it is not a problem with modern 24-bit converters.

Digitizers for a Higher Dynamic Range

The Ramp digitizer has a practical limit of 16-bit dynamic range. This is not enough for most applications in seismology. Imagine a network recording local earthquakes. A magnitude two earthquake is recorded at 100-km distance with a maximum count value of 200, which is a lower limit if the signal should be recorded with a reasonable signal-to-noise ratio. What would be the largest earthquake at the same distance that could be recorded with a 16-bit converter before clipping? A 16-bit converter has a maximum output of 32,768 counts or 164 times larger. Assuming that magnitude increases with the logarithm of the amplitude, the maximum magnitude would be $2.0 + \log(164) = 4.2$. So a higher dynamic range is needed. In the following, some of the methods to get a higher dynamic range will be described.

Oversampling for Improvement of the Dynamic Range

The method of oversampling to improve the dynamic range of a digital signal consists of sampling the signal at a higher rate than desired,

Recording Seismic Signals, Fig. 7 Unfiltered and filtered record of seismic background noise in a residential area in western Norway on a hard rock site. The recording is made with a 4.5-Hz geophone and a 16-bit ADC at

a sample rate of 50 Hz. The filter is an eight-pole Butterworth filter with no phase shift (Figure from Havskov and Alguacil 2010)

low-pass filtering the digital signal, and resampling (decimating) it at a lower rate. Qualitatively what happens is then that the quantization errors of the individual samples in the oversampled trace are averaged over neighboring samples by the low-pass filter and the averaged samples therefore have more accuracy and consequently a higher dynamic range. In the frequency domain, the effect of oversampling is to spread the quantization noise over a wide frequency band, thus lowering its spectral density (e.g., Proakis and Manolakis 1992).

As an example, a digital recording of seismic background noise will be used; see Fig. 7. The top trace shows the unfiltered record which has a maximum amplitude of 5 counts. It is possible to see that there is a low-frequency signal superimposed on the cultural noise signal. After filtering, a smooth record of the microseismic noise with a typical period of 3 s is clearly seen. The microseismic noise is globally present and generated by ocean waves. Although the maximum amplitude is only 1.8 counts, it is clear that the resolution is much better than one count.

Noise in the signal, combined with oversampling, is therefore helping to increase the dynamic range. However, with a completely constant, noise-free signal, oversampling would not be able to increase dynamic range. Normally,

it is no problem to have noise in the signals, rather the contrary. However, in some designs, a Gaussian white noise of amplitude 0.5 LSB is added to the signal to get a higher dynamic range. This is also called dithering; see Fig. 8.

It is seen that the averaging of the signal without noise does not remove the quantization steps. It simply rounds them out a little.

This description of oversampling is very simplified. For more details, see, e.g., Scherbaum (2007) and Proakis and Manolakis (1992).

Sigma-Delta ADC (SDADC)

All ADCs will digitize the signal in steps, so, even with the highest resolution, there will be a quantization error. The idea behind the SDADC is to digitize with a low resolution but high sampling rate so as successive samples are highly correlated, get an estimate of the signal level, add the quantization error to the input signal, get a new estimate, etc. This process will continue forever, and the actual value of the input signal is obtained by averaging a large number of estimates. In this way, a higher resolution can be obtained than it is possible with the original ADC in much the same way as described with oversampling. Most SDADCs are based on a one-bit oversampling ADC that in reality is just a comparator that can determine if the level is

Recording Seismic Signals, Fig. 8 Effects of dithering and averaging on a sine wave input (Modified from www.ni.com/white-paper/3016/en/)

negative or positive. This ADC can be made very fast and accurate and is essentially linear.

To understand how a sigma-delta works, it is useful to describe first what is called delta modulation, which was used to transmit voice signals in early times of digital telephony. In Fig. 9, we can see the principle. The signal is compared with a staircase signal generated in the following recursive form: if, at each clock pulse, the input signal is higher than the level of the staircase signal, a 1 is output from the A/D converter. This is now fed back to the staircase generator which increases its output with one step. If the level of the signal is smaller than the staircase signal level, a 0 is output, and the staircase signal is decreased by one step. If the signal is constant, a continuous stream of 1,0,1,0... is then the output. The step height needs to be high enough (or the sample rate high enough) to be able to follow the maximum signal slope, but the higher the step, the higher is the noise generated in the

flat zones of the signal. The output level of the D/A determines the maximum signal level that can be digitized.

The staircase function is proportional to the time integral of the output code. This output signal is itself a digital approximation of the time derivative of the input signal. Thus, integrating the delta code will decode it and give an approximation of the input signal. The output signal can also be said to approximate the level differences between one sample and the next.

This is used in the sigma-delta modulator (Fig. 10). In this case, the staircase generator is not needed, since the feedback integration and the input signal integration are performed by the unique integrator after the sum point, and simple 1-bit A/D and D/A do the job.

The device operates in discrete time. The digital converter, the integrator, and the digital-to-analog converter are all synchronized and controlled by a logic circuit (not shown).

Recording Seismic Signals, Fig. 9 Delta modulation. *Left*, simplified schematic of a delta modulator. *Right*, the input signal (blue) is compared with a staircase signal (red) that increases by a step when the input signal is

above its previous value and decreases otherwise. The *bottom* shows the output of the modulator which can be used to generate the staircase signal which is an approximation to the real signal

Recording Seismic Signals, Fig. 10 Simplified overview of the functional blocks of a sigma-delta ADC

After a time step, the signal y from the A/D (in this example, a simple voltage comparator) is converted back to analog with the digital-to-analog converter (D/A). The output from the D/A is a signal of plus or minus the maximum input voltage (or reference voltage). This signal is subtracted from the present input signal x . The difference b is integrated. Since it is a discrete time circuit, this means that b multiplied with the time step is added to the previous value to give c . Due to the multiplication with the time step, the level of c is small. c is then feed into the one-bit A/D converter. Its output is 1 (high) for a nonnegative c signal and 0 for a negative c signal.

In Fig. 11, it is seen how it works for a constant input voltage of 1.5 V. Step 1: The integrated value is initially zero so 2.5 V is added to the signal b (Fig. 10). Step 2: The value at b is now $1.5 + 2.5$ which integrated becomes $(1.5 + 2.5)/64 = 0.06$. Step 3: A positive value at c (0.06) gives 1 at y , and 2.5 V is subtracted from the

signal at x so b is now $1.5 - 2.5$, and $(1.5 - 2.5)/64 = -0.016$ is added to the previous value of 0.06. This process repeats itself with the same negative steps until c becomes negative and a new positive pulse is generated. The average of the digital output at y is proportional with the analog input at x , and in this case, there are many 1's and few zeros so the output signal is clearly positive. If the input voltage is closer to the positive reference voltage, the negative steps will be smaller so there will be many more 1s compared to zeros. A zero input voltage would give an equal number of 0's and 1's to the average output signal is also zero (remember 0–1, represent the range -2.5 to 2.5 V). A negative input would give more 0's then 1's.

Figure 12 shows a signal that goes from positive to negative, and the proportion of 1s and 0s in the output code y varies accordingly. It can be shown theoretically (e.g., Proakis and Manolakis 1992; Aziz et al. 1996) that the output exactly represents the input if the sample rate is high enough.

Recording Seismic Signals, Fig. 11 Signals at several points of the simplified sigma-delta converter shown in Fig. 10 for an input voltage of 1.5 V. *ck* is the sampling clock. *b* is the difference between the actual input and the D/A output *d* for the previous step, *d* is the output of the digitizer converted to analog voltage. *c* is the integrator

output. *s* is the filtered output. The sample rate is low in this example (64 samples per second, sps) in order to make the figure clear, and the step length is then 1/64 s. The maximum input voltage span (or reference voltage) is ± 2.5 V

Recording Seismic Signals, Fig. 12 Signals at several points of the simplified sigma-delta converter shown in Fig. 10 for a variable input voltage *x*. The signals' labels are the same than in Fig. 11. *y* is the output digital code

The output *y* of the sigma-delta modulator is low-pass filtered to *s* with a digital filter and decimated to a much lower output rate with high resolution. For instance, an internal sample rate of 3×10^5 sps and an output data rate of 100 sps may be typical values.

In practice, the integrator in high-resolution converters is multiple, typically 3–5 order. An *n* order SDAC has *n* difference-integrator circuits following each other. The effective dynamic range of a SDADC increases with the integrator order and the oversampling ratio.

Recording Seismic Signals, Fig. 13 An example of aliasing due to insufficient sample rate. A 5-Hz signal is digitized at a rate of 2 Hz. The digitization points are indicated with *red dots*. Depending on where the samples

are taken in time, the output signal can either be interpreted as a straight line (*yellow points in middle*) or a 1-Hz sine wave (*red*) (Figure from Havskov and Alguacil 2010)

Real SDADCs can be very complicated and there are many variations of the design compared to the description here. A typical SDADC uses several stages of digital filtering and decimation, so there are many ways to get the final signal. High-resolution SDADCs are inherently slow, with output data rates limited to about 1,000 (sps).

Aliasing

It is seen that there is a quantization error in amplitude due to the discrete resolution. Similarly, errors can also be introduced due to the discrete steps taken in time. Figure 13 shows an example of a 5-Hz signal digitized with a rate of 2 Hz or a sample interval of 0.5 s. The 2-Hz digitization rate is missing out on several oscillations that are simply not seen. If the samples happen to be taken on the top of the 2-Hz cycles, the digitized output signal will be interpreted as a 1.0-Hz sine wave. If the samples were taken a bit later, the output would be a constant level. From this example, it is clear that, in order to “see” a sine wave with frequency f , the sampling rate must be at least $2f$. In the above example, the sample interval must be at least 0.1 s or a sample rate of 10 Hz in order to “see” the 5-Hz signal. Thus, the general rule is that the signal must be sampled at a rate twice the frequency of the signal of interest. Or, in a given time series, it is only possible to recover signals at frequencies half the sampling rate. This frequency is called the Nyquist frequency.

The effect of sampling with a too low rate is not just that information of higher-frequency signals is lost, but more seriously that the high-frequency signals inject energy into the signals at frequencies lower than the Nyquist frequency. In the above example, the pure 5-Hz signal creates a nonexistent 2-Hz signal of the same amplitude as the 5-Hz signal so the digitized output would be completely distorted and have a wrong frequency content. This effect is called aliasing. The only way to avoid this problem is to make sure that the input signal does not contain energy above the Nyquist frequency. So an ADC must have a low-pass filter (an anti-alias filter) to remove unwanted high-frequency energy above the Nyquist frequency prior to the sampling. Alternatively, the sampling rate must be at least double the highest frequency with non-negligible content in the signal.

For traditional ADCs, the anti-alias filtering is done using an analog filter before digitization, while for ADCs with built-in oversampling and processing, most of the anti-alias filtering can be done digitally. Ideally, the anti-alias filter should remove all energy above the level of the LSB at the Nyquist frequency which is possible with high-order digital filtering.

Digital Recorder

The ADC has now been described as a component providing digital data readable by

Recording Seismic Signals, Fig. 14 Main units of a seismic recorder. There are no flow arrows between the units since all can have two-way communications. The GPS can be connected to the digitizer or the recorder. The

power supply may be common for all elements, or each may have its own regulator, but usually the power source is unique (e.g., a battery) (Figure from Havskov and Alguacil 2010)

a computer, in analogy with an amplifier providing an analog signal to be “received” by some analog storage medium. This data now has to be recorded by some computer. Currently, most digital recorders store all the data, the so-called continuous recording. One day of 24-bit (3 bytes) data of one channel, 100-Hz sampling rate, gives $3,600 \times 24 \times 100 \times 3 \approx 26$ Mb of data which is typical for seismological applications. For one month, a three-channel recorder would then record 2.4 Gb or 1.2 Gb if using a compressed recording format. In its simplest form, this can be done with a simple program dumping the data to disk on a general PC. For field use, this is usually not convenient due to power consumptions and that the equipment is not suitable for outdoor use.

The main elements of a digital seismic recorder are seen in Fig. 14.

The main tasks of the seismic recorder can be summarized as follows:

- Read data from one or several digitizers. The digitizers can be internal or external but usually internal.
- If digitized data do not have a time stamp, the recording computer must perform the time stamping of the data. This means that a time reference must be connected to the computer, usually a GPS receiver. If the recorder is connected to Internet, time

Recording Seismic Signals, Fig. 15 Centaur recorder from Nanometrics. The size is $20 \times 14 \times 8$ cm and the weight is 2.0 kg

- stamping could also be done with NTP (Network Time Protocol).
- Store data on a storage medium. Usually, there is a ring buffer, which means that after some time (hours to months depending on the size of the storage medium), the data is overwritten. For limited memory systems, there might not

Recording Seismic Signals, Fig. 16 Two examples of strong motion recorders with internal accelerometers. *Left:* model Etna from Kinometrics, with its lid removed. It is fixed to the floor with a central screw. On the back left

side the internal battery is located, and at the right side the sensors are seen. *Right:* model CMG-5TD from Güralp Systems anchored to the ground with its leveling base. The two cables are for power supply and GPS antenna

be a ring buffer, but just recording of declared events with some pre-event memory. Optionally, the data logger may simply stop recording when the storage media is full, instead of overwriting the oldest data.

- Check incoming data for seismic events (perform triggering) and store only real events. This might not be needed if the system has a large ring buffer but is often an option in order to get a quick idea of recorded events. Most present recording systems will record in continuous form.
- Provide communication with the outside world for change of parameters and download of data. This could be download of files with single events as well as a continuous stream of real-time data to be received at some data center.
- Act as a central recorder. In this case, the digitizer is in the field and it sends the data in real time to a central computer which then records the data.

Different manufacturers have constructed recorders using different types of computers,

Recording Seismic Signals, Fig. 17 The RefTek130S-01, a complete seismic station with six sensors, GPS, and a recorder. A short-period seismometer is seen to the right. The diameter is 22 cm and the height is 15 cm. The weight is 3.2 kg including battery and sensors (Figure from www.reftek.com)

ways of communications, and storage media, which has sometime made it difficult to interconnect different recorders and to use data from different recorders together. Fortunately, there is now more standardization and a typical up-to-date recorder using the most common standard can be as follows:

- The digitizer will have a resolution of 24 bits and be time stamped with a GPS.
- The recording computer will use a single-board Linux computer and record the data in a continuous form in MiniSeed format (the most used standard, see SEED 2012). The recorder will record the signal in flash memory, typical 64 Gb so a standard system will be able to record continuously for more than 4 years (3 channels, 100-Hz sample rate).
- Communications: Standard Ethernet with TCP/IP and serial lines (RS232) so the recorder can be connected to Internet and also accessed by modem or locally with a PC.
- Real-time transmission by Ethernet: The most common standard is to use SeedLink (www.seiscomp3.org). This standard can, by buffering, recover data from communication breakdown of hours to days so a central computer will not lose data in case of communication fault.
- Physical: The recorder will be waterproof, typically use 1 W of power, and have a weight of a few kg.

Seismic recorders for field use can be divided into three types:

A freestanding recorder with external sensors.

This is the most common type and can be used with all types of sensors. An example is shown in Fig. 15. This is a compact recorder with low-power consumption (1 W without Ethernet). It has a Linux operating system, a dynamic range of 140 dB, all required communication ports, high capacity fixed, and removable internal flash storage. It supports several communication

standards, can record MiniSeed, and communicates with SeedLink.

Strong motion recorders with built-in accelerometers.

This kind of recorder can be very simple with only registration of the events and no continuous recording, and it can be as sophisticated as a standard recorder. It is also very widespread and thousands have been built. Figure 16 shows two examples of recorders with built-in accelerometers, both with many units installed: Kinematics Etna, with only events recording capability, and Güralp CMG5-TD, with both events and continuous recording.

A seismic recorder with built-in seismometers.

This is not so common since, to protect the sensor from mechanical disturbances, it is often desirable to separate the seismometer from the recorder. On the other hand, it can be very convenient for field work. Figure 17 shows an example. This is a compact 6-component recorder with a short-period sensor, an accelerometer, and a battery built in. It only uses 0.4 W.

Summary

Recording of seismic signals starts with the process of digitizing the signal from the seismic sensor and doing an accurate time stamping of the data. The data is then sent to a recording computer which will store the data for days or years depending on recording capacity. The computer might also detect the events and/or send the data to a computer center in real time for central recording.

Centroid moment tensor; Earthquake mechanisms and tectonics; Fault plane solution; Mechanisms of earthquakes; Seismic moment tensor inversion

Introduction

The seismic moment tensor is the complete mathematical representation of the movement on a fault during an earthquake, comprising of the couples of forces that produced it, the description of the fault geometry, and its size by means of the scalar seismic moment M_0 .

The computation of seismic moment tensor has become a widely diffused activity because of the relevance of this kind of data in seismotectonic and geodynamic studies and, in more recent times, because it allows obtaining rapid information about a seismic event immediately after its occurrence. This progress has been possible with the advent of modern standardized instruments since the early 1960s, above all of the very broadband seismographic stations that started to record in the late 1970s. Furthermore, time after time, the easier availability of digital data impressed a strong incentive to improve the procedures of source parameter computation.

Seismic moment tensor solutions are used to identify the activated faults during a seismic sequence, to understand their kinematics, and consequently to sketch the short-term possible evolving scenarios. Catalogs collecting all definitive seismic moment tensor solutions are one of the most relevant databases for geodynamic and seismotectonic studies at really different scales. At worldwide scale, the Global Strain Map (Kreemer et al. 2003, <http://gsrm.unavco.org/>, last access November 27, 2014) or the World Stress Map (Heidbach et al. 2008; <http://dc-app3-14.gfz-potsdam.de>, last access November 27, 2014) includes seismic moment tensor data to describe the worldwide strain and the stress maps. Effectively geodetic data measures the motion, borehole measurements give stress directions, and seismic moment tensors, in addition with geologic studies if available, give indications of the acting tectonic regimes.

At regional scale, merging seismic moment tensors with geology and geodesy data provides a picture of the present-day kinematics and tectonics also for a very complex region, e.g., Serpelloni et al. (2007) for the Western

Mediterranean. At local scale, the contribution of seismic moment tensors data is essential to identify the active faults and to study their kinematic behavior. Examples can be found for almost all well-known faults in the world, starting from the San Andreas and concerning the Mediterranean, the Marmara Sea in Turkey (Kinscher et al. 2013) or the Atlantic Ocean close to Portugal coasts (Stich et al. 2007) or along the Southern Apennines in Italy (Cucci et al. 2004).

The possibility to determine the seismic moment tensor of an earthquake is strongly related to the magnitude of the event and the threshold of the used computation method. For large global earthquakes, several research groups and agencies in the world produce routinely seismic moment tensors. Those having at present the longest experience and the greatest regularity are primarily the Global CMT (previously Harvard CMT) group at Lamont–Doherty Earth Observatory (LDEO) of the Columbia University (Dziewonski et al. 1981; see entry on “► Long-Period Moment-Tensor Inversion: The Global CMT Project”) and the United States Geological Survey (USGS, Sipkin 1994). These groups both started in the 1980s, employing different methods but having in common the use of teleseismic waveforms. More recently, also the source parameters produced by GEOSCOPE group at the *Institut de Physique du Globe de Paris* (Vallée et al. 2011) and those from GEOFON Earthquake Information Service (Cesca et al. 2010) are constantly available.

The Global Centroid Moment Tensor catalog (GCMT) produces centroid moment tensor (CMT) solutions for events that occurred since 1976 (Dziewonski et al. 1981; see entry on “► Long-Period Moment-Tensor Inversion: The Global CMT Project”). CMT solutions are routinely calculated for events located worldwide with a moment magnitude of M_w 5.0 and above. The final monthly catalog is published online about 4 months later (www.globalcmt.org). The traditional GCMT method uses long-period body and mantle waves (those with a period longer than 135 s); most of published solutions are calculated using an approach that, excluding minor modifications, is the same of its inception, in the 1980s.

In the last few years, only GCMT solutions are computed inverting also for intermediate period surface waves, variation that allows a lowering of the magnitude threshold down to 5.0 (see entry on “► Long-Period Moment-Tensor Inversion: The Global CMT Project”).

The United States Geological Survey (USGS) seismic moment tensor solutions have been determined routinely starting from 1993 (Sipkin 1994) for worldwide events with a magnitude greater than 5.5, using a technique different from the one employed for the computation of the Global CMTs. Namely, the “optimal filter design theory” has been applied to compute the source parameter solutions using only the long-period P-waveform vertical components, low-pass filtered at 20 s. The use of vertical components simply allows for shorter time to recover the necessary data, accelerating the source parameter computation. USGS moment tensors are available since 1980 because they have been computed backward in time. Presently, USGS seismic moment tensor solutions are regularly published in the *Physics of the Earth and Planetary Interiors* journal (PEPI) up to 2004 and at the same time are available on a dedicated web site (<http://earthquake.usgs.gov/earthquakes/eqarchives/sopar/>, last access November 27, 2014).

The list of agencies or research groups active in producing seismic moment tensors becomes longer when the magnitude threshold and the geographic scale changes from worldwide to regional. Moreover, the availability of these data is much more scattered, especially if we compare it among different areas. In fact, complete datasets with a long-time continuity are naturally available just in regions where low-to-moderate earthquakes are considered relevant and are recorded by a consistent number of seismographic stations, such as in Japan (Grid MT, Tsuruoka et al. 2009; NIED CMT, Kubo et al. 2002), in California (TMTS, <http://seismo.berkeley.edu/mt/>, last access November 27, 2014), or in the European–Mediterranean region (European–Mediterranean RCMT catalog or GFZ moment tensor solution dataset).

Here the efforts developed in the last decades in Europe and in the Mediterranean region for the

computation of regional seismic moment tensors for moderate-magnitude events are described. The earthquakes characterized by moderate energy release are those that more frequently affect this region. They are relevant given the high density of population and the concentration of human activities (e.g., tourism) where the seismic hazard is sometime incredibly high due to historical and social reasons. After a review of the applied techniques and the available catalogs for the Mediterranean region, a description of the European–Mediterranean RCMT catalog is added, followed by a review of typical tectonic trends of this region.

Seismic Moment Sensors for the European–Mediterranean Region

In the European–Mediterranean region, also a moderate-magnitude event may be particularly relevant due to the high seismic hazard of most of this region. The heterogeneity of the distribution of population since historical time, in some area particularly dense, together with a great variety of human activities, with tourism as one of the more relevant economy income, should be combined to a diffuse building vulnerability due to historical and social reasons.

Several agencies compute source parameters also for moderate-magnitude earthquakes for the whole region or for subregions. Figure 1 shows two maps downloaded from the European–Mediterranean Seismological Center (EMSC) web page (<http://www.emsc-csem.org/Earthquake>, last access November 27, 2014) showing all seismic moment tensors quickly computed by several research groups and published rapidly online after earthquake occurrences. Despite the moderate magnitude that is lower than 5.5 in both cases shown in the maps, at least five focal solutions are available. These results are obtained applying different methods and somehow different data; the added value is the quick check of their stability obtained by comparing them.

For moderate-magnitude earthquakes, the more constant contributors of quick solutions for the whole European–Mediterranean region are those

computed by the Quick RCMT project (Pondrelli et al. 2012 and references therein; <http://www.bo.ingv.it/RCMT>, last access November 27, 2014) and by the German Research Centre for Geoscience (Cesca et al. 2010; <http://geofon.gfz-potsdam.de/eqinfo/list.php?mode=mt>, last access November 27, 2014). Quick RCMTs are obtained with a semiautomatic process (Pondrelli et al. 2012) activated by the alerts sent by the EMSC after any events of interest, in this case any with a magnitude greater than 4.5 occurring in the geographic window between 10°W and 40°E of longitude and 25°N to 60°N of latitude. The magnitude threshold lowers to 4.0 for seismic events that occurred in Italy. Seismograms of body and surface waves mainly recorded at regional distance (within 15°–20° from the epicenter), collected from IRIS (<http://www.iris.edu>, last access November 27, 2014) and WebDC EIDA Data Center (<http://www.webdc.eu>, last access November 27, 2014), are used to invert for seismic moment tensor computation. The inversion process, better explained in the next paragraph, is an evolution of the Global CMT method (see entry on “► Long-Period Moment-Tensor Inversion: The Global CMT Project”). A visual inspection is done before the distribution online of inversion results, through several web sites, such as the <http://autorcmt.bo.ingv.it/quicks.html> (last access November 27, 2014) or the EMSC event web page (Fig. 1).

GFZ seismic moment tensor solutions are computed automatically using a spectral analysis technique that, at successive inversion steps, adopts the appropriate range of frequency, norm definition, and inversion method, to reach the best fitting source parameters (Cesca et al. 2010). Any solution is published online at <http://geofon.gfz-potsdam.de/eqinfo/> (last access November 27, 2014) and in the EMSC event web page. Since 2011, within this project, the seismic moment tensors for earthquakes with a magnitude threshold that changes with distance are constantly determined. Indeed, for European earthquakes, the GFZ dataset includes the source parameters for events with a magnitude greater than 4.5 and occasionally also for lower magnitude, down to 4.0.

Regional Moment Tensor Review: An Example from the European–Mediterranean Region, Fig. 1 A screenshot of two typical EMSC web pages, as examples of the several seismic moment tensor solutions computed for two events, September 16, 2013 M 5.3 in Greece and

October, 6, 2013 M 5.3 in Romania. Moment tensor solutions are quickly computed immediately after the earthquake occurrence and published routinely on the EMSC web page <http://www.emsc-csem.org/Earthquake>

Out of RCMT or GFZ MT, other contributors compute seismic moment tensors for earthquakes of the Mediterranean region. At the Swiss Seismological Service, in Zürich, the ETHZ moment tensor project is active. Before 2010, it guaranteed the automated computation of seismic moment tensors for large earthquakes worldwide and for large- to moderate-magnitude events in the European–Mediterranean region (http://www.seismo.ethz.ch/prod/tensors/mt_autom/index_IT, last access November 27, 2014; Bernardi et al. 2004). Computations were done using a consolidated technique based on the inversion of surface waves in the spectral domain (Giardini et al. 1993). Since 2010, the ETHZ moment tensor project produces automatically the seismic moment tensor for all events with M_l greater than 3.5 occurred in the Swiss region only. They adopted the Dreger and Helmberger (1993) method, adapted to local conditions and updated with local Green functions. This algorithm inverts the complete three-component broadband displacement waveforms to estimate a point-source solution.

This computation method is presently used also at the Instituto Geográfico Nacional seismic moment tensor project (IGN, <http://www.ign.es/ign>, last access November 27, 2014, Rueda and Mezcuá 2005). The source parameters for the seismicity having a magnitude greater than 3.0 of the Iberian Peninsula, Gibraltar Strait, and Alboran Sea, Northwestern Africa, in particular Canary Islands and Morocco, are determined using three-component seismograms recorded from the IGN seismographic network. The obtained solutions are then published quickly on the dedicated IGN web page and in the EMSC event web page.

Similarly, it occurs in the TDMT@INGV project for Italian seismicity. Since 2006, seismic moment tensors are rapidly computed also for smaller magnitude events, down to 3.5, using the Italian National Network seismic recordings and the Dreger procedures with the Green functions calibrated for the Italian peninsula (Scognamiglio et al. 2009; <http://cnt.rm.ingv.it/tdmt.html>, last access November 27, 2014).

In the Southeast Mediterranean areas, the Aristotle University of Thessaloniki (AUTH, Roumelioti et al. 2007) for the Greek seismicity and surrounding regions, and the Kandilli Observatory (KOERI) for Turkish seismic activity, have implemented dedicated procedure based on Dreger methods. The results of these analyses are regularly published on the EMSC event web site, such as the examples reported in Fig. 1. It is only at the National Observatory of Athens (NOA, Konstantinou et al. 2010) that source parameters are computed with a different technique, a linear time-domain moment tensor inversion method with a point-source approximation (Randall et al. 1995; Melis and Konstantinou 2006). Moment tensors are determined for all earthquakes, with a magnitude occasionally lower than 4.0, occurring in Greece and surrounding regions since 2005 (<http://bbnet.gein.noa.gr/HL/seismicity/moment-tensors>, last access November 27, 2014).

The amount of projects active at present to obtain rapidly good quality seismic moment tensors in the European–Mediterranean region enhances the importance given to source parameters in real-time seismic sequence scenarios. However, all datasets collected by each project, even if merged altogether, lack the geographic and temporal continuity that are requested to define a catalog to be used in seismic hazard or seismotectonic studies. The European–Mediterranean RCMT catalog only reached these features described in the following.

A Consolidate Example: The European–Mediterranean RCMT Catalog

The RCMT project is the most relevant and most continuous initiative for seismic moment tensor computation on the European–Mediterranean scale. It starts with the 1997–1998 Central Italy seismic sequence. At that time, Arvidsson and Ekström (1998) have already developed the *regional* version of centroid moment tensor (CMT) computation technique, based on the modeling of surface waves of intermediate period (35–100 s) recorded at regional distance

(within 10° between station and epicenter). The method focuses on the determination of a centroid moment tensor also for moderate-magnitude events, e.g., a magnitude between 4.5 and 5.5, while standard CMT points to solve for earthquakes with a magnitude greater than 5.5.

When the RCMT project activated, each seismic moment tensor solution was determined using three-component seismograms recorded only by the very broadband stations of the regional network named MedNet. Seismograms were obtained through modem connection and computations were made using data from five to ten stations (Ekström et al. 1998). The first solutions in quasi-real time, namely the Quick RCMTs, have been available about 5 years later, in 2002, and regularly published in the MedNet web page, now not updated anymore. At the same time, the first version of the European–Mediterranean RCMT catalog became available (Pondrelli et al. 2011). RCMT solutions were obtained using three-component seismograms from all reachable very broadband stations, belonging to regional networks, e.g., MedNet or GEOFON (now GFZ) or worldwide networks, e.g., GSN IRIS/IDA network. Seismograms from stations closer than 90° were generally used and when the magnitude were lower than 5.0, only stations at distances up to 60° were included in the inversion.

In the firstly used RCMT algorithm, source parameters were recovered inverting for the complete three-component waveforms, including fundamental mode surface waves (Love and Rayleigh). This part of the seismic signal is, at regional distance, the one with greatest amplitude, but it is difficult to model because of its high sensitivity to crustal heterogeneities. On the other hand, modeling surface waves recorded at short distance allows the computation of moderate-magnitude events. This is the main advantage of RCMT algorithm and the reason of its extensive use in some regions, with respect to traditional CMT method.

In the RCMT computation process, the source excitation has been always computed in PREM (Dziewonski et al. 1981). Synthetic seismograms

Regional Moment Tensor Review: An Example from the European–Mediterranean Region, Fig. 2 On the left, a group of waveforms (real in blue and synthetics in dotted red) for stations located at regional distance (within 10°) for an event with Mw 4.8 occurred in Sicily in January 1998. On the right, a group of waveforms belonging to an earthquake Mw 5.2 occurred in Southern Greece

in October 1998, for stations located at teleseismic distance. For each waveform, the station name, the component (LHZ: vertical, LHN: N–S component, LHE: E–W component), the distance from the epicenter, and the azimuth, that is, the direction at which is located the station with respect to the epicenter, clockwise starting from the north, are reported

for fundamental mode surface waves have constantly determined by propagating the source pulse through the high-resolution global phase velocity models of Ekström et al. (1997). Normal mode summation was used only to model the overtone contribution, mostly evident when teleseismic distance waveforms were included in the inversion (Fig. 2). The observed and synthetic seismograms matched after a low-pass filtering with a cutoff down to 35 s and three to five iterations to minimize the misfit, estimating the moment tensor elements and a centroid location.

Since 2004, RCMTs are determined inverting also for long-period body waves, modeled by summation of the normal modes of the Earth corrected for large-scale three-dimensional mantle structure, in the same manner as in the Global

CMT Project (see entry on “► [Long-Period Moment-Tensor Inversion: The Global CMT Project](#)”).

An example of observed and synthetic seismograms for different distances is shown in Fig. 3. Body waves are included in the RCMT inversion when the distance between the epicenter and the station is large enough to separate body wave-train arrival from the surface wave one, maintaining at the same time a good signal-to-noise ratio. The use of the two different wave types has a stabilizing effect on the centroid location, in particular, and this is true for the earthquakes occurring near the border of our study region, e.g., out of Gibraltar Strait, since for these events the azimuthal station coverage is sometimes poor. Band-pass filtering is done between 40 and 150 s in velocity for body

Regional Moment Tensor Review: An Example from the European–Mediterranean Region, Fig. 3 Two examples of real (*blue*) and synthetic (*red*) waveforms for body and surface waves produced by the more recently used RCMT process computation. These data are for a Mw 5.2 earthquake, occurred in Southern Italy in

December 2014, recorded by two stations located at a different distance from the epicenter. In the lower panel, for surface waves, rotated horizontal components and the longitudinal and transverse components (LONG and TRANS) are used

waves, while for surface waves band-pass value changes with the magnitude, starting from 50 to 150 s for earthquakes with a magnitude of 5.5 to 35–75 s when the magnitude lowers to 4.5. Surface wave filtering is done always on the displacement signal.

At present, the RCMT computation procedure starts for all earthquakes occurring in the European–Mediterranean region with MI (Richter or local magnitude) greater than 4.5 or 4.0 for the Italian peninsula. The semiautomatic *pypaver* process (Pondrelli et al. 2012) produces a first version of Quick RCMT that is published, after a visual inspection, on the dedicated web pages (see previous paragraph for detail). After 3–4 months, all earthquakes, for which a trial to compute a QRCMT has been attempted, will be revised and all stable solutions are included in the European–Mediterranean RCMT catalog. It is searchable at <http://www.bo.ingv.it/RCMT/searchRCMT.html> (last access November 27, 2014).

RCMTs are available in the European–Mediterranean RCMT catalog since 1997 up to the present, for events with magnitudes greater than 4.5, for a total of nearly 1700 seismic moment tensor solutions. The geographical space is limited to 25°–60° N in latitude and 10°W–40°E in longitude. For the Italian peninsula and Cyprus Island only, a backward extension of this catalog in time (up to 1976) and in magnitude (down to Mw 4.0) exists (Pondrelli et al. 2006; Imprescia et al. 2011; <http://www.bo.ingv.it/RCMT>).

The RCMT, definitive or quick, is considered stable when: (1) a minimum of seismograms of three stations azimuthally well distributed (with an angular distance of about 120° each other) is available, (2) the focal mechanism remains stable during five iterations needed to determine the centroid location, (3) the total root mean square of the misfit between seismograms and synthetics averaged for all station used is lower than 0.4, (4) the difference between initial and final coordinates is lower than 0.3°, and (5) the moment tensor should have a small non-double-couple component. This last point is quantified using thresholds arbitrarily used to define a non-double-couple moment tensor (see entry on

“► Long-Period Moment-Tensor Inversion: The Global CMT Project”).

In addition, a quality flag is given to all RCMT solutions. The A flag is given to all RCMT solutions that show full compliance to all criteria listed above, while the other letters (up to D) describe decreasing levels of quality. The B flag corresponds to moment tensors that have a difference between preliminary and final coordinates greater than 0.3° and lower 0.5°. If the variation is greater than 0.5°, the coordinates are kept fixed along the inversion and the flag becomes C. Coordinate variation is usually due to low quality of azimuthal distribution of stations when calculating RCMT for moderate-magnitude earthquakes. Flag D is given only when the obtained moment tensor has a high non-double component due to low signal-to-noise ratio. Changes in the difference between preliminary and final coordinates and large non-double-couple component can be considered indicators of complex seismic sources for large-magnitude events, but in the case of RCMT, computed mainly for moderate-magnitude earthquakes, they are commonly related to the low-quality, mainly noisy, seismographic data. The expedient of quality flags allowed being less severe in the quality criteria check when RCMT computation is applied to old or smaller earthquakes, as in the case of the Italian peninsula or for Cyprus Island.

The success ratio between the obtained RCMT solutions and the number of seismic events for which a computation trial is done is about 60 %. Several factors influence this ratio. Most of the earthquakes listed in the seismicity catalogs are tagged with a magnitude, in general MI (Richter or local magnitude), significantly larger than our resulting moment magnitude Mw; thus they are often too small to produce the necessary signal at long period. Another limiting factor is that moderate-magnitude events often are foreshocks or aftershocks of a seismic sequence. Consequently, waveforms include the signal of more than one event in the same time window, avoiding the possibility to separate single seismic source solution. Moreover, during a seismic sequence, seismograms are often strongly

Regional Moment Tensor Review: An Example from the European–Mediterranean Region, Fig. 4 Map of all the European–Mediterranean RCMT catalog solutions starting from January 1997 to December 2013. Focal mechanisms (*shaded areas*) change color with respect to the hypocentral depth of the earthquake (see legend at *top right*): black focal mechanisms represent shallower seismicity, while deeper events have a *red to yellow* beach

ball. Deeper events are mostly located close to the Gibraltar Strait, in the Southern Tyrrhenian Sea, and along the Hellenic Trench and South Turkey to Cyprus Island. In the background, the seismicity of the last 10 years from the European–Mediterranean Seismological Center (EMSC, <http://www.emsc-csem.org>) is mapped in *yellow* and major tectonic features are drawn in *white* (Barrier et al. 2005)

contaminated by the signal of the main events. Furthermore, a low quality of preliminary geographic location influences the final solidity of the RCMT. Earthquakes occurring in the marginal areas of the Mediterranean (out of the Gibraltar Strait or along part of the Northern Africa) often lack the sufficient recordings to reach as well a stable location and this weakens also definitive RCMT quality.

To ascertain the stability and quality of RCMT solutions, they have been compared to other seismic moment tensors computed with different conditions, finding a very good correspondence although station recordings and modeled waveforms were substantially different. Since the project started, RCMT solutions have been constantly compared with traditional CMT solutions and, successively, with other similar datasets. Several comparisons have been done

with ETH and GFZ data. A recent example is given in Cesca et al. 2010, where their seismic moment tensors are shown together with other catalog solutions, in particular RCMT (in the paper named MedNet, from the name of seismographic network data used at that time), Global CMT (still named Harvard CMT), ETH, and USGS seismic moment tensor solutions. In Fig. 4, the complete European–Mediterranean RCMT catalog is reported. Although surface wave signal is expected to be a little part of the seismogram in case of deep sources, it is sufficient to obtain stable RCMT solutions (Fig. 4).

The European–Mediterranean RCMT catalog considerably increases the number of earthquake moment tensors available in the European–Mediterranean region. For instance, the Global CMT catalog includes 424 events for the period 1997–2012 for this region, while adding RCMT

quadruples the total number of solutions (Fig. 5). This result is particularly significant for the Mediterranean region, where moderate-magnitude events have sometimes a greater impact with respect to other parts of the world, as a consequence of the particular density of population and human activities and the heterogeneity of seismic risk plan development, related to important social difficulties.

Focal Mechanisms and Tectonic Systems in the Mediterranean

The Alpine–Mediterranean region is characterized by a really complex active tectonics, connected to the 100 My convergence between Africa and Eurasia plates, also involving several microplates (e.g., Adria and Anatolian ones). Earthquake focal mechanisms, representing the wide range of tectonic regimes acting here, contribute to the understanding of the active tectonics and yield fundamental information.

Seismicity in the Mediterranean area is rather diffuse and is characterized by mostly moderate energy release. Moderate-magnitude events are therefore particularly important because they are more widely spread than the relatively infrequent large earthquakes. This is evident comparing the two maps of Fig. 5, where 17 years of RCMT data give information for several regions (e.g., Central Europe, Pyrenees, Tunisia) not documented by 37 years of CMT data, as a consequence of the lowering of the magnitude threshold.

The most relevant geodynamic feature of the European–Mediterranean region is the tectonic boundary between Africa and Eurasia plates (yellow line in Fig. 6): starting from the Atlantic Ocean, it crosses from west to east of this area, entering the Mediterranean Sea through the Gibraltar Strait, following the coast of Northern Africa up to Sicily, then following the main mountain belts, such as the Apennines, the Alps, the Dinarides, and the Hellenides, and going further to the Hellenic Trench and the Cyprus Arc, moving toward east up to the Caucasus. The Africa and Eurasia plates converge for a long time, but in spite of generating solely a mountain

belt between them, a partitioning of the boundary gave life to several small geodynamic systems that altogether accommodated the plate convergence. Most of the basins that together compose the entire Mediterranean Sea, namely, the Alboran Sea, the Balearic Basin, the Tyrrhenian Sea, and the Aegean Sea (Fig. 6), opened as back-arc basins of different subducting systems active in different times. Only the Southern Tyrrhenian and the Hellenic subducting systems are still active as testified by deep earthquakes occurring down to 400 km of depth and more (Fig. 4). This amazing geologic history has been reconstructed using geological and geophysical data, starting from a realistic sketch of the present-day deformation, drawn with a major contribution of seismic moment tensor dataset (e.g., Vannucci et al. 2004).

In some parts of the Mediterranean, the complexity of geodynamic activity is shown by the coexistence of different focal mechanisms in short distances, few tens of km (Figs. 6 and 7). One example is the Northern Apennines, where normal, thrust, and transpressive (a mixture of strike-slip and compressive focal mechanisms) earthquakes occur together; another case is in the Northern Aegean Sea, where normal and strike-slip events represent the intersection between the transcurrent Northern Anatolian Fault motion occurring together with the extension of Aegean and Western Turkey region (Fig. 6a, b). The part of the Mediterranean where the plate collision exhibits a nearly constancy is Northwestern Africa, where most of earthquakes are thrust (Fig. 6c). However, also in this zone, strike-slip and few extensional events occur because even in this part of the boundary, the two main plates involved did not get in contact directly; they are separated by the Alboran Sea that is interpreted as a back-arc basin of a subduction system anciently active beneath Gibraltar Strait. Another part of the boundary where thrust earthquakes prevail is along the Hellenic Trench, where the African plate subducts under the Eurasian one (Fig. 6d). In fact, around it all types of focal mechanisms exist, related to the strike-slip faults that partition the trench (e.g., the Kefalonia Fault) or the

Regional Moment Tensor Review: An Example from the European–Mediterranean Region, Fig. 5 Map of all CMTs (*above*) and RCMTs (*below*) available in the European–Mediterranean region. CMT focal mechanisms are for earthquakes that occurred starting from 1977 to

2013 with a magnitude greater than 5.5, while RCMT solutions are for smaller seismic events, down to magnitude 4.0, occurred from 1997 to 2013. For seismicity and tectonic features in the background, see Fig. 4

Regional Moment Tensor Review: An Example from the European–Mediterranean Region, Fig. 6 Central map: main tectonic features of the Mediterranean region. Red lines are the principal active tectonic structures (Barrier et al. 2005). In yellow, a sketch of the plate boundary between Africa and Eurasia. GS, Gibraltar Strait; Al, Alboran Sea; BB, Balearic Basin; S, Sardinia; Tyr, Tyrrhenian Sea; AS, Adriatic Sea; HeT, Hellenic

Trench; AeS, Aegean Sea; An, Anatolian microplate; NA, Northern Anatolian Fault; EA, Eastern Anatolian Fault; Cy, Cyprus Island. In the four enlarged maps, all RCMTs and CMTs together for each zone are reported: (a) Northern Apennines; (b) transition between Northern Aegean and Marmara Sea following the Northern Anatolian Fault; (c) Alboran Sea and Northern Africa; (d) Northern Hellenic Trench (KF: Kefalonia Fault)

Regional Moment Tensor Review: An Example from the European–Mediterranean Region, Fig. 7 (a) Thrust (in red), (b) strike-slip (in green), and (c) extensional (in blue) seismic moment tensors for event with a

hypocentral depth shallower than 50 km mapped separately to better draw the different tectonic regimes active in the European–Mediterranean region. For seismicity and tectonic features in the background, see Fig. 4

extensional tectonics active in the front and back (e.g., in the Corinth Gulf).

In Fig. 7, in three separated maps, all thrust (in red), strike-slip (in green), and extensional (in blue) focal mechanisms are shown: these views help to study at larger scale the active tectonic styles. Thrust beach balls represent the compressive tectonic style and their distribution shows where the boundary between tectonic plates collides. This type of deformation occurs along a nearly continuous and narrow zone in Northern Africa, from Morocco to Northern Sicily, with two interruptions at the Gibraltar Strait (Fig. 6c) and south of Sardinia. Another continuous part of the tectonic boundary characterized by compressive features is along the eastern part of the Adriatic Sea, along Dinarides and Hellenides belts and partially around the Hellenic Trench. Other minor regions characterized by a compressive deformation are in the Northern Apennines and around Cyprus Island.

The distribution of strike-slip earthquakes is more diffuse (green in Fig. 7). In the Mediterranean, major strike-slip faults bound the Anatolian microplate (Fig. 6): at north the Northern Anatolian Fault can be clearly followed from the Marmara Sea to the Caucasus at east, while at southeast the Eastern Anatolian Fault runs from Cyprus Island to the Caucasus. Out of these two important tectonic structures, strike-slip focal mechanisms are however all along the Africa–Eurasia plate boundary. This is due to the fact that strike-slip earthquakes occur along the tectonic structures that dislocate different parts of the plate boundary and they accommodate its partitioning. The Africa–Eurasia plate boundary has a snake shape, and all of its curves are the concrete image of this partitioning, and in correspondence of most of them, strike-slip earthquakes prevail.

Normal focal mechanisms (blue in Fig. 7) characterize the areas where the lithosphere is affected by an extensional deformation, that is, where basins are opening or mountain belts are subjected to a collapse. In the Mediterranean, the two regions characterized by extensional tectonics are the Apennines and the whole Aegean Sea and surrounding regions (Fig. 6). Extensional

earthquakes typify also the Pyrenees and the Central Europe basins, such as the Rhine Graben.

A more careful description of earthquakes focal mechanisms in closer relation with tectonic structures of the European–Mediterranean region can be found in the *Atlas of Mediterranean Seismicity* (Vannucci et al. 2004).

Summary

The Mediterranean region is characterized by a complex tectonics and a widely distributed deformation, connected with the convergence between Africa and Eurasia plates. Smaller earthquake seismic moment tensors are extremely important to understand the geodynamics. The several methods used in this region to compute seismic moment tensors are described, with the main attention to RCMT computation process and to the European–Mediterranean RCMT catalog, the most relevant and most continuous initiative on regional scale.

Introduction

The *raison d'être* of most concrete structures is to create horizontal surfaces for use or occupancy (floors, a bridge deck, etc.) or, sometimes, for protection (a roof). Most of the mass, which generates the inertia forces in an earthquake, resides on these horizontal elements. Gravity loads travel from these elements to the ground via vertical elements, typically columns. Beams or girders often span between the columns to facilitate the collection of gravity loads from the horizontal surfaces and their transfer to the columns (Fig. 1). Concrete walls are often used in buildings (Fig. 2) to brace them laterally against second-order ($P-\Delta$) effects and to resist horizontal forces.

Walls can resist a horizontal earthquake very efficiently. And so does the combination of columns and floor beams – which exist anyway for the gravity loads – into frames. So, beam-column frames are the most common type of earthquake-resistant construction. Concrete walls are normally supplementary, because, unlike in masonry construction, it is not cost-effective to collect and transfer the floor gravity loads through concrete walls alone. So, the prime focus of this chapter is on concrete frames and walls, in their role as components of an earthquake-resistant system.

Inertia forces should find their way to the foundation via a smooth and continuous path in the structural system. From that point of view, cast in situ concrete is much better for earthquake-resistant construction than prefabricated elements – of concrete, steel, or timber – assembled on site: the connections between such elements create discontinuities in the flow of forces. So, cast in situ construction is the technique of choice for earthquake-resistant concrete structures, especially buildings; besides, monolithic construction is the quintessential use of concrete. For these reasons, section “[Frame, Wall, or Dual \(Frame-Wall\) Systems in Earthquake-Resistant RC Buildings](#),” below has cast in situ construction as the true focus, although precast systems are in principle covered as well. The special aspects of earthquake-resistant precast buildings are addressed in section “[Precast Concrete Systems](#)” supplementing section “[Frame, Wall, or Dual \(Frame-Wall\) Systems in Earthquake-Resistant RC Buildings](#),” in this respect. Section “[Floor diaphragms](#)” is devoted to concrete floors in their role as diaphragms, covering both fully cast in situ floors and those incorporating precast elements.

This chapter discusses the overall philosophy of earthquake-resistant reinforced concrete building design. It is intended for the experienced design professional and assumes familiarity with codes and frequently recurring problems in practice.

Frame, Wall, or Dual (Frame-Wall) Systems in Earthquake-Resistant RC Buildings

Frame Systems

Features of the Seismic Behavior of RC Frames

Walls resist the seismic overturning moments and the shears directly, through bending moments and shears, respectively, in the wall itself. By contrast, in a frame, the seismic overturning moment is resisted, not by the column moments but by axial forces in the columns (tensile at the windward side of the plan, compressive at the opposite – i.e., leeward – one, Fig. 3a).

Reinforced Concrete Structures in Earthquake-Resistant Construction, Fig. 1 Building with two-way frame system and foundation through (a) footings with two-way tie-beams and (b) two-way foundation beams

Reinforced Concrete Structures in Earthquake-Resistant Construction, Fig. 2 Frame-wall system with walls resisting lateral loads in both horizontal

directions; deep foundation beams for the walls; foundation of interior columns through (a) footings with two-way tie-beams and (b) two-way foundation beams

The column bending moments resist indirectly the seismic story shears: the algebraic difference between the bending moments at the top and the bottom of each column produces its contribution to the seismic shear of the storey (Fig. 3b). So, the seismic response of frame members is governed by flexure or strictly speaking by

normal action effects: bending moments and axial forces.

In a regular plane frame under lateral loading, the column inflection points are close to the story mid-height (Fig. 3b). Therefore, at that end of the column where the bending moment is larger, the shear span (moment-to-shear ratio) is

Reinforced Concrete Structures in Earthquake-Resistant Construction, Fig. 3 Typical seismic internal forces in a regular plane frame: (a) axial forces; (b) bending moments

normally between one-half and two-thirds of the column clear height. So, the most crucial components of a RC frame, its columns, normally have a shear span ratio (ratio of shear span to column depth) greater than 2.5. In beams, the most critical end is the one which, under earthquake loading, is under the largest hogging (negative) moment. The beam shear span ratio there is normally in the order of 3. For such values of shear span ratio, the inelastic behavior and failure of RC frame members are governed by flexure and are inherently ductile (provided that these members are designed not to fail in shear before their end sections yield in flexure).

Advantages and Disadvantages of RC Frames for Earthquake Resistance

The main advantage of RC frames for earthquake resistance is that, provided that they are capacity designed for plastic hinging in the beams and against preemptive shear failure of any member, their flexural behavior lends itself to the development of large global ductility and deformation capacity. Moreover, if there are several plane frames in the building, each one with several bays, the lateral-force-resisting system has high redundancy and offers multiple load paths. Therefore, with appropriate detailing of the end regions of their members, frames can be easily designed to resist strong earthquakes through

global ductility, rather than thanks to strength. For this reason, they are the structural system of choice in high seismicity regions, such as the Western USA and Japan. However, one can fully trust only fairly regular frames, having concentric beam-column connections. Strongly irregular frames and eccentric connections may have poor seismic performance. Besides, they are not sufficiently covered by present state of the art.

Although the seismic behavior of beams, columns, and frames made of reinforced concrete has been studied experimentally and analytically much more thoroughly than that of walls or wall systems, there are still significant uncertainties and gaps of knowledge about it. Examples are listed under disadvantage no. 4 below.

The advantages of RC frames for earthquake resistance may be summarized as follows:

1. The members of RC frames are inherently ductile.
2. Two-way frame systems, consisting of several plane frames in each horizontal direction with several bays each, have very high redundancy and multiple load paths.
3. Frames place few constraints on the architectural design, especially of the façade.
4. Provided that the frame has concentric connections and regular geometry, there is little uncertainty about its seismic response, because:
 - The seismic performance of frames and frame members is well known and understood, thanks to thorough experimental and analytical studies;
 - Frames are fairly easy to model and analyze for design purposes.
5. Certain features make frames attractive and cost-effective for earthquake resistance:
 - Beams and columns are needed in buildings anyway to support the gravity loads; so, why not use them for earthquake resistance as well?
 - Columns have strength and lateral stiffness against both horizontal components of the seismic action.
 - It is easy to design the foundation of smaller vertical elements (notably columns) than of larger ones (walls), with each foundation element transferring to the ground a small fraction of the seismic base shear.

Frames have also disadvantages for earthquake-resistant design:

1. Frames are inherently flexible and the size of their members is often governed by the inter-story drift limits under a moderate earthquake for which limitation of damage to structural and nonstructural elements is sought.
2. Column counterflexure within the same story may lead to soft-story mechanisms and a “pancake” type of collapse (Fig. 4).
3. Detailing of frames for ductility requires workmanship of high quality and strict supervision on site (especially for fixing the dense reinforcement and placing and compacting the concrete through the beam-column joints of two-way frames).
4. There are certain elements of uncertainty about the seismic response and performance of frames:
 - The effects of eccentric connections or strongly irregular layouts in 3D are not sufficiently known.
 - There is considerable uncertainty about the magnitude of the effective slab width in tension: it is pointed out that slab bars which are in this effective flange width and are parallel to the beam increase its flexural capacity for hogging moment and hence the beam capacity design shears, as well as the likelihood of plastic hinging in the columns.
 - The behavior of columns of two-way frames under the complex loading conditions (cyclic biaxial bending with varying axial force) to which they are subjected during real earthquakes is poorly known.
 - In two-way frames subjected to real earthquakes, columns that have been capacity-designed against plastic hinging may well form plastic hinges owing to the biaxial moment demands from beams connected to them in the two horizontal directions.

Reinforced Concrete Structures in Earthquake-Resistant Construction, Fig. 4 Soft-story mechanism due to plastic hinges in the columns of a frame (*left*) and pancake type of collapse (*right*)

Conceptual Seismic Design of RC Frames

The location of frames in plan, the span lengths, and often the depth of beams are normally controlled – sometimes even dictated – by architectural and functional considerations, as well as by design for gravity loads alone. However, the structural designer is normally left with considerable latitude for decisions and choices on the basis of seismic design considerations alone.

If a regular plane frame has:

- A constant span length in all bays,
- Beams and interior columns with constant cross section in each story, and
- An (effective) rigidity of the two exterior columns equal to 50 % of that of interior ones,

then the elastic seismic bending moments at the ends of all beams in the story will be the same, while those in the two exterior columns will be just half of the bending moments in the interior columns. In the elastic range, the seismic overturning moment will be resisted by axial forces in the exterior columns alone, approximately equal to the ratio of the seismic overturning moment at story mid-height to the distance between the axes of these columns. If members are dimensioned for the elastic seismic moments, all beam ends in a story will be subjected to about the same inelastic chord rotation demand; all columns, interior or exterior, will also develop about the same inelastic rotation demand at the story bottom; the same at column tops. This uniformity reduces uncertainty

about the distribution of seismic action effects among the members of the frame and within them.

Too short or too long bay lengths should be avoided:

- If the beam span is very long, the beam top reinforcement over the supports may be governed by factored gravity loads, rather than by seismic design. This penalizes the capacity design moments of columns at the joints and the capacity design shears of beams and columns. It produces flexural overstrength in beams with respect to the corresponding seismic demands and creates uncertainty about the inelastic response and the plastic mechanism. If plastic hinges do indeed form in a long beam, the large hogging moments at beam ends due to the concurrent gravity loads may prevent reversal of the inelastic flexural deformations there. Although the primary effect of non-reversal is positive, there is a collateral negative one: inelastic elongations accumulate in the reinforcement and the beam gradually grows longer, pushing out its supporting columns and possibly forcing exterior ones to separate from exterior beams at right angles to the elongating one(s). Last but not least, if the average clear beam span in the story is much longer than the clear storey height, then the cross section of the beam may have to be increased excessively for the story to meet the drift limits for purposes of damage control.

- Very short beam spans cause very high seismic shears in the beams, both from the seismic analysis and from the capacity design of the beam in shear. If the span is short in some bays but long in others, the high seismic shears in the short beams generate a large variation of the axial force in the adjoining columns upon reversal of the direction of the seismic action. This reversal will also cause an almost full reversal of the sign of shear at the ends of the short beam(s), because the concurrent gravity loads produce insignificant shear forces in short beams, especially as these beams usually support the secondary direction of floor slabs. A full reversal of high shears may exhaust the shear capacity in both diagonal directions or cause sliding shear failure along through-depth cracks at the end section(s) of the beam. Design against such shear effects may require diagonal reinforcement in the beam or shear reinforcement at $\pm 45^\circ$ to the beam axis. Last but not least, short beams have a low shear span ratio (often below 2.5) and, unless diagonally reinforced, low deformation capacity.

For the most common story heights and for ordinary gravity loads, the optimum beam span in earthquake-resistant buildings is between 4 and 5 m. Span lengths should be as uniform as possible within each frame.

RC Wall Systems

Definition of a Wall

Design codes define a concrete wall as a concrete vertical element with an elongated cross section. A limit of 4.0 for the aspect ratio (long-to-short dimension) of a rectangular cross section is conventionally adopted by most design codes to distinguish walls from columns. If a composite cross section consists of rectangular parts, one of which has an aspect ratio greater than 4, then this element is also classified as a wall. With this definition on the basis of the cross-sectional shape alone, a wall differs from a column in that:

- It resists lateral forces mainly in one direction, notably parallel to the long side of the section.

- It can be designed for such a unidirectional resistance by assigning flexural resistance to the two edges of the section (“flanges” or “tension and compression chords”) and shear resistance to the “web” between them, as in beams.

So for the purposes of flexural resistance and deformation capacity, one may concentrate the vertical reinforcement and provide concrete confinement only at the two edges of the section (Fig. 5). (If the cross section is not elongated, the vertical element is called upon to develop significant lateral-force resistance in both horizontal directions, then it is meaningless to distinguish between “flanges” on one hand, where vertical bars are concentrated and concrete is confined, and “web” on the other, where they are not).

The above definition of “walls” is consistent with concrete design codes and appropriate for dimensioning and detailing at the level of the cross section. It is not very meaningful though, in view of the intended role of “walls” in the structural system and of the correct practice in design, dimensioning, and detailing of walls, notably as entire elements and not just at the cross-sectional level. Seismic design often relies on walls for the prevention of a story mechanism in their long direction, without any verification that plastic hinges form in beams rather than in columns. Nevertheless, walls can enforce a beam-sway mechanism only if they act as vertical cantilevers (i.e., if their bending moment diagram does not change sign within at least the lower story(s) and they develop a plastic hinge only at the base (at the connection to the foundation)). As a matter of fact, unless the wall bending moment attains two values of large magnitude but of opposite sign within the full height of the wall (let alone within the same story), the wall cannot develop two plastic hinges in opposite bending (positive and negative) along its height and a story mechanism between them. Whether a “wall,” as defined above, will indeed act as a vertical cantilever and form a plastic hinge only at its base depends not so much on the aspect ratio of its section but primarily on how stiff and

Reinforced Concrete Structures in Earthquake-Resistant Construction, Fig. 5 Typical layout of reinforcement in wall section

strong the wall is relative to the beams it is connected to at story levels. For concrete walls to play their intended role, the length dimension of their cross section, l_w , should be large, not just relative to its thickness, b_w , but in absolute terms too (see Fig. 2 for examples). To this end, and for the beam sizes commonly found in buildings, a value of at least 1.5 m for low-rise buildings or 2 m for medium- or high-rise ones is recommended here for l_w .

A vertical element with a cross-sectional aspect ratio less than 4.0 (i.e., defined conventionally as a “column”) may work in an earthquake as a vertical cantilever and form a plastic hinge only at the base, if it is connected at story levels with very flexible beams or with no beams at all (as in flat-slab systems). However, normally the moment resistance at the base of such a vertical element is small, so that, given its long shear span (moment-to-shear ratio) there, it cannot contribute significantly to the base shear of the building. Moreover, its lateral stiffness is also low, so it is not effective in reducing inter-story drifts for damage limitation or P- Δ (second-order) effects. At the other extreme, vertical elements with cross sections sufficiently elongated to be classified as walls, but connected at story levels with very stiff and strong beams, may act as frame columns rather than as vertical cantilevers.

Optimal Length of Walls

If the lateral-load-resisting system comprises only walls, the full seismic overturning moment at the base of the building is resisted directly by the (sum of) bending moments at the base of the walls, instead of indirectly by their axial forces. So at the base of a wall, the bending moment is large and the shear span (M/V ratio), L_s , long. If the beams are very flexible compared to the walls, each wall works as a vertical cantilever

subjected only to horizontal forces at story levels. Then L_s is about equal to $2/3$ of the total wall height, H_{tot} . For the usual beam sizes, L_s is about half of H_{tot} if the length l_w of the wall section is fairly large or about equal to 1.5 times the story height if l_w is short, near the limit of 4 times the width, b_w .

The shear strength of a concrete element is roughly proportional to its cross-sectional depth, h . Therefore, lumping the shear resistance into a few vertical elements with large values of h , instead of distributing it to many small-sized ones, does not save materials. On the other hand, the rigidity of RC members is roughly proportional to h^3 . So lumping the lateral stiffness into few vertical elements, rather than spreading it to many small ones, is very cost-effective. Using few walls with a large cross section is also cost-effective from the point of view of moment resistance and vertical reinforcement, because for a given base shear, V , and concrete volume per linear meter of building height, i.e., for a given wall cross-sectional area, the reduction of the shear span ratio, L_s/h , reduces the total vertical reinforcement ratio necessary to resist the wall base moment (Fardis 2009). As explained in the previous paragraph, for a wall with a fairly large value of $h = l_w$, the shear span, L_s , is roughly a known fraction of the building height. Therefore, the total vertical reinforcement ratio necessary to resist the wall base moment can be reduced by increasing h as much as reasonably feasible, i.e., by lumping the vertical elements into a few large walls. The optimum value of h is the one that gives values of L_s/h in the range between 2.5 and 3.0, below which the cyclic behavior of the wall and its ultimate deformation may be adversely affected by shear. For the typical value $L_s \approx 0.5H_{\text{tot}}$, a shear span ratio equal to $L_s/h = 3.0$ gives $l_w = h \approx H_{\text{tot}}/6$, i.e., $l_w \approx n_{\text{story}}/2$ for a typical story height of 3 m.

Reinforced Concrete Structures in Earthquake-Resistant Construction,

Fig. 6 Rocking of a large wall: (a) single rigid wall; (b) wall on footing connected to normal-size tie-beams

Foundation of Walls

The base section of a large and strong wall has a high moment resistance. It is difficult to transfer this large moment capacity to the ground through isolated footings. The maximum bending moment that an isolated footing can transfer to the ground is slightly less than the moment causing the footing to overturn, which is equal to $0.5NB$, where N is the vertical force and B is the dimension of the footing in the direction of bending. If the wall section is long, the parallel dimension of its footing is not much longer than the wall length $h = l_w$. So the maximum value of the nondimensional base moment in the wall, $\mu \equiv M/(bh^2f_c)$, that can be transferred by an isolated footing is $\mu \leq 0.5v$, where $v \equiv N/(bhf_c)$ is the nondimensional axial load at the base of the wall. Because walls have relatively low values of v (in the order of $v \approx 0.05$), the maximum value of μ that can be transferred to the ground through an isolated footing is also very low, in the order of the nondimensional moment at cracking of the wall base section (as the tensile strength of concrete is typically around 10 % of its compressive strength, f_c). Therefore, in order to develop its moment resistance at the base, a strong wall:

- Should be provided with a very large isolated footing, which is not cost-effective and introduces large uncertainty about the seismic response (it will uplift, following a nonlinear

relation between bending moment and uplift rotation which is hard to quantify, at least within everyday design practice), or

- Should be fixed at the top of a box-type foundation provided for the building as a whole (see section “[Box Type Foundation Systems](#)”), which fixes all walls at their base and maximizes their effectiveness

An isolated footing will uplift from the ground when the moment at its bottom exceeds the value corresponding to decompression at its edge. Then it starts rocking, with the value of the moment at its base approaching, but never reaching, the overturning moment of the footing, $0.5NB$, where B is the dimension of the footing in the vertical plane where rocking takes place (Fig. 6a). The wall and its footing will rock as a rigid body (Fig. 6b). As the seismic action is not static but dynamic, rocking is a very stable mode of response for the wall, provided that the concentrated force at the edge of the footing does not bring about bearing capacity failure of the foundation soil.

The relationship between the lateral force and the horizontal displacement during rocking under cyclic loading is nonlinear but nearly elastic, following an approximately bilinear envelope and recentering to approximately zero displacement for zero force. Therefore, rocking of a wall on an isolated footing may be considered as

a ductile mode of seismic response, almost as ductile as that of a fixed wall with a flexural hinge at the base. For this reason, some international guideline documents acknowledge for rocking a force reduction factor of the same order as that applying to ductile structural response. However, there is so much uncertainty about rocking – notably about its implications for the seismic action effects within the superstructure – that it cannot be reliably quantified and modeled in the context of earthquake-resistant design of wall systems.

Large RC Walls

Walls of large cross-sectional length which are fixed at the base exhibit certain features in their seismic response which resemble rocking of a wall with isolated footing. This is because, owing to the small magnitude of the wall axial force, the neutral axis of the cracked (or yielded) base section of the wall is very close to the edge of the section (Fig. 7) and far from its centroid (CG in Fig. 7). Therefore, flexure of the wall significantly lifts the centroid of the gross section and, with it, the tributary mass of the building supported on the wall. So part of the kinetic energy is temporarily and harmlessly converted to potential energy of these tributary masses, in lieu of damaging deformation energy of the wall itself. Besides, the end of any beams framing into the part of the wall section outside the compression zone is also raised (Fig. 7). So long as the other end of the beam is not lifted by the same amount, the beam shear force has a stabilizing effect on the wall, acting downward, increasing the wall axial compression to the benefit of its instantaneous strength, stiffness, and stability, while reducing the resultant moment on the section.

The above beneficial aspects of the wall behavior are due to the large horizontal dimension of the wall, combined with the no-tension feature of cracked concrete (similar to the interface between a footing and the ground) that causes the flexural rotation to take place about a pivot near the edge of the wall section. These phenomena are of purely geometric origin (due to coupling of the rotations with the vertical

Reinforced Concrete Structures in Earthquake-Resistant Construction, Fig. 7 Schematic plan view of wall section

displacement at the centroid of the wall section) and are neglected in ordinary geometrically linear analyses of the response, even when the analysis accounts for material nonlinearity; they are sources of good performance of structural systems consisting of large walls that are usually not taken into account.

Walls with a large horizontal dimension compared to their height cannot be designed effectively for energy dissipation through plastic hinging at the base, as they cannot be easily fixed there against rotation with respect to the rest of the structural system. Design of such walls for plastic hinging at the base is even more difficult, if the wall is monolithically connected with one or more transverse walls which are also large enough to be considered merely as “flange(s)” or “rib(s)” of the first wall. Walls with large horizontal dimensions will most likely develop little cracking and inelastic behavior under the design seismic action. Cracking will be mainly horizontal, at construction joints at floor levels. Flexural yielding, if it occurs, will also take place mainly there. Then the lateral deflections of large walls, acting as vertical cantilevers, will be produced by a combination of:

- A rotation of the foundation element of the wall with respect to the ground, most often with uplifting
- Similar rotations at sections of horizontal cracking and (possibly) flexural yielding at one or more floor levels, with the wall swaying as a stack of rigid blocks

Reinforced Concrete Structures in Earthquake-Resistant Construction, Fig. 8 Examples of systems of large walls

Owing to the rather low axial load level in large walls, these rotations will take place about a “neutral axis” very close to the compressed tip of the foundation element or to the compressed edge of the wall section at locations of cracking and (possibly) yielding. Such rotations induce significant uplift of the centroid of the sections, raising the floor masses tributary to the wall and the ends of beams framing into it to the benefit of the global response and stability of the system. Moreover, rigid-body rocking of the wall with its footing promotes radiation damping, which is particularly effective in reducing the high-frequency components of the input motion.

Eurocode 8 (CEN 2004) recognizes the ability of large walls to withstand large seismic demands through their geometry, rather than via strength and hysteretic dissipation due to vertical reinforcement. It defines a “large lightly reinforced wall” as a wall with a horizontal dimension, l_w , at least equal to 4.0 m or to two-thirds of its height, h_w (whichever is less) and gives it a special role. It also provides special design and detailing rules for such walls, allowing much less reinforcement than in “ductile walls,” provided that they belong in a lateral-load-resisting system consisting mainly of such walls (Fardis et al. 2005). Figure 8 shows examples of systems of large walls.

Walls with Non-rectangular Section or with Openings

Most of what has been said so far in section “**RC Wall Systems**,” as well as almost the entire body of knowledge about the cyclic behavior of concrete walls, is about walls with two-way-

symmetric rectangular or quasi-rectangular section (barbelled section, i.e., rectangular with each edge widened into a rectangular or square “column” or compact flange – with an aspect ratio of less than 4 – to enhance the moment resistance and prevent lateral instability of the compression zone). Such walls are modeled and dimensioned as prismatic elements with an axis passing through the centroid of their section. Lacking a better alternative, the same practice is applied when a rectangular wall runs into or crosses another wall at right angles to create a wall with a composite cross section of more than one rectangular parts – each part with an aspect ratio greater than 4 (L-, T-, C-, H-shaped walls, etc.). Such walls have high stiffness and strength in both horizontal directions. So they are subjected to biaxial bending and bidirectional shears during the earthquake. They are more cost-effective than the combination of their constituent parts as individual rectangular walls. However, present-day knowledge of their behavior under cyclic biaxial bending and shear is very limited, and the rules used for their dimensioning and detailing still lack a sound basis. Moreover, their detailing for ductility is complex and difficult to implement on site. For this reason, it is strongly recommended to make limited use of such walls in practical design. Designers choosing to use non-rectangular walls should opt for fairly simple geometries (e.g., one-way-symmetric C-section or two-way-symmetric H-section).

Large openings should be avoided in ductile walls, especially near the base, where a plastic hinge will form. If they are necessary for

functional reasons (e.g., for doors or windows), openings should be arranged at every floor following a very regular pattern, turning the wall into a coupled one, with the lintels between the openings serving and designed as coupling beams.

Advantages and Disadvantages of Walls for Earthquake Resistance

On the basis of what has been said so far in section “[RC Wall Systems](#),” the advantages of RC wall systems for earthquake-resistant design may be summarized as follows:

1. Walls are inherently stiff, so:
 - They are insensitive to the presence and any adverse effects (global or local) of masonry infills.
 - They prevent or limit damage in frequent or occasional earthquakes.
2. Walls offer excellent protection against collapse, as the lack of wall counterflexure within a story makes a soft-story mechanism physically impossible (Fig. 6b).
3. The seismic behavior and performance of individual walls is less sensitive than that of frames to lower quality design or poor workmanship on site.
4. Geometric effects and phenomena in large walls are favorable for the seismic response and performance.
5. All things considered, RC walls are more cost-effective for earthquake resistance than RC frames.
5. To avoid large eccentricities or low torsional stiffness of the stories, walls that contribute significantly to lateral stiffness and strength (e.g., those around service cores housing elevators, stairways, vertical piping, etc., close to the center in plan, or large perimeter walls) should be counterbalanced in plan by other elements with similar lateral stiffness and strength.
6. It is difficult to provide an effective foundation to a wall, especially with isolated footings.
7. There is large uncertainty about the seismic response of wall systems:
 - The cyclic behavior and seismic performance of RC walls and wall systems are less known than those of frames, because experimental research is more difficult to carry out and analytical models need to be more advanced and sophisticated.
 - The effects of rocking or of the rotations about the neutral axis of the wall cannot be accounted for reliably in practical design.
 - Walls are more complex to model, analyze, dimension and detail in practical design (especially those with a non-rectangular section).

Wall systems also have disadvantages for earthquake-resistant design:

1. They are inherently less ductile than RC beams or columns, more sensitive to shear effects, and harder to detail for ductility.
2. They offer limited redundancy and few alternative load paths.
3. They limit the freedom of the architectural layout, especially at the façade.
4. It is not cost-effective to use RC walls alone to support the gravity loads of the building; some beams and columns are needed anyway for that purpose.

Dual Systems of Frames and Walls

Both walls and frame systems, each have their advantages and disadvantages as lateral-load-resisting systems (see sections “[Advantages and Disadvantages of Walls for Earthquake Resistance](#)” and “[Advantages and Disadvantages of RC Frames for Earthquake Resistance](#)”, respectively). Although walls seem to have a better balance of advantages and disadvantages, one should keep in mind that there are almost always beams and columns in a building to carry gravity loads to the ground. It is a waste not to use them at all for earthquake resistance. So, it is cost-effective for earthquake resistance to combine within the same structural system frames and walls.

Many buildings combine frames and walls in their lateral-load-resisting system; sometimes the frames clearly dominate, sometimes the walls, while often none is clearly dominant; it is in such cases that the system is considered as

a dual (wall-frame) system. Eurocode 8 (CEN 2004) uses as a formal criterion to distinguish between systems the percentage of the seismic base shear taken, according to the linear analysis for the seismic action, by all the frames in the system or by all its walls:

- A “dual system” is one in which the percentage of the seismic base shear taken by the frames or the walls is between 35 % and 65 %; moreover, such a system is classified as a “wall-equivalent dual” or a “frame-equivalent dual,” if the percentage of the base shear taken by walls is between 50 % and 65 % or between 35 % and 50 %, respectively.
- If frames take more than 65 % of the seismic base shear, the lateral-load-resisting system is a “frame system.”
- If walls take more than 65 % of the seismic base shear, the lateral-load-resisting system is a “wall system.”

Dual systems combine the high strength and stiffness and insensitivity to soft-story effects of wall systems (advantages no. 1 and 2 of walls in section “[Advantages and Disadvantages of Walls for Earthquake Resistance](#)”) with the large ductility, deformation capacity, and redundancy of frames (advantages no. 1 and 2 of frames in section “[Advantages and Disadvantages of RC Frames for Earthquake Resistance](#)”). The walls offer protection from nonstructural damage in frequent, moderate earthquakes and help to meet the inter-story drift limits prescribed in seismic design codes. The frames may act as a second line of defense in very strong earthquakes, in case the deformation capacity of the inherently less ductile walls is exhausted and some walls lose a good part of their strength and stiffness. In view of this potential backup role of frames, US codes require the frames of dual systems to be designed for at least 25 % of the design seismic action, no matter the relative stiffness of the walls and the frames in the system. If this condition is met, US codes entitle dual systems of high ductility frames and walls to as high a value of the force reduction factor, R , as in frame systems.

Eurocode 8 (CEN 2004) assigns also the same value of the force reduction factor, q , to “frame systems” and to “dual systems,” i.e., to any system where frames take at least 35 % of the design base shear according to a linear seismic analysis.

Frames subjected to lateral loading have shear-beam-type lateral displacements, with the floors sliding horizontally with respect to each other. Inter-story drifts follow the height wise pattern of story seismic shears: they decrease from the base to the roof. By contrast, walls fixed at the base deflect laterally like vertical cantilevers, i.e., their inter-story drifts increase from the base to the roof. If frames and walls are combined in the same structural system, floor diaphragms impose on them roughly common floor displacements. As a result, the walls restrain the frames at lower floors, undertaking there the full inertia loads of the floor. Near the top of the building the frame is called upon not only to resist the full floor inertia loads but also to hold back the wall, which – if acting alone – would have developed a very large deflection at the top. In rough approximation, the walls of dual systems may be considered to be subjected to:

- The full inertia loads of all floors
- A concentrated force at the roof level, in the reverse direction with respect to the peak seismic response and the floor inertia loads

The magnitude of the concentrated force at the top exceeds that of the resultant inertia loads in the upper floors (i.e., of the story seismic shear there). Consequently, in the upper stories, the walls are often under reverse bending and shear with respect to the stories below (Fig. 9a–c). The frame may be considered to be subjected to just a concentrated force at the top, equal and opposite to the one applied there to the wall(s) and in the same sense as the floor inertia loads. Then the frame has roughly constant seismic shear in all stories and hence about the same bending moments in all of them (Fig. 9d, e). As a result, even when the cross-sectional dimensions of frame members are kept the same in all stories, their reinforcement requirements for the seismic

Reinforced Concrete Structures in Earthquake-Resistant Construction, Fig. 9 Seismic moments and shears in wall-frame system with box-type of basement: (a) schematic moment (M) and shear (V) diagrams in interior wall of seven-story building plus basement; (b)

example M-diagram in interior wall of six-story wall-frame building with two basement storeys; (c) V-diagram of wall in (b); (d) example M-diagram in interior frame of building in (b), (c); (e) V-diagram of frame in (d)

action do not increase from the top to the ground level. As a matter of fact, column reinforcement requirements may even decrease in lower stories, thanks to the favorable effect of the increased axial force on flexural strength. Therefore, in dual systems, column size should not decrease toward the roof.

Dual systems are geometrically more complex than frame or wall systems and have a more complicated seismic response than either one of them. Therefore, there is larger uncertainty about their seismic behavior and performance. This uncertainty is the main (if not the only) inherent drawback of dual systems against pure frame or wall

systems. Their conceptual design should aim at reducing this uncertainty. For instance, as the diaphragms of dual systems are called upon to impose common floor displacements to the two systems by transferring horizontal forces from the frame to the wall or vice versa, they should be thicker and stronger within their plane than what is required in pure frame systems. Another uncertainty arises from any rocking of the wall (s) at the base (Fig. 6). Such rocking shifts part of the story shears from the wall(s) to the frame. Rocking of wall footings with uplift is an intrinsically complex phenomenon, which cannot be reliably modeled in the framework of seismic

design practice. Underestimation of such rocking leads to unsafe design of the frames, while overestimation is unsafe for the wall(s). So, a prudent design would eliminate rocking in dual systems by providing full fixity of the walls at the foundation.

Note that in a system consisting only of walls, the distribution of seismic shear between them will be practically unaffected by the rotation of all the walls at the foundation level; the rotation will only increase the absolute magnitude of story drifts. The effect of the rotation of foundation elements is even smaller in pure frame systems: any rotation of the footing of a frame column has practically no consequences beyond the ground story; moreover, such a rotation will be much smaller than in a wall footing, because the higher axial load of the column resists uplift; more importantly, the smaller the cross section of a vertical element compared to the plan dimensions of its footing, the smaller its rotation. So, it is the design of systems that combine the two types of elements (walls and columns) that suffers from increased uncertainty, owing to the rotations of footings with respect to the ground.

Tall buildings often have a dual system comprising a strong wall near the center in plan (around a service core housing elevators, stairways, vertical piping, etc.) and stiff and strong perimeter frames. In such a system outrigger beams may be used to advantage, increasing the global lateral stiffness and strength of the system and mobilizing the perimeter frames against the seismic overturning moment.

Flat-Slab Frames

Beamless slabs (“flat slabs” called “flat plates” in North America, if supported on columns directly, without drop panels or column capitals) provide larger clear story height, unobstructed passage of services under the slab, and freedom for irregular layout of the column grid and potential modification of the layout of partitions. Moreover, if labor is expensive, they may be cost-effective for residential or office buildings. Most common are solid cast-in-place slabs, sometimes post-tensioned with bonded or unbonded tendons. Waffle slabs with drop panels around the columns

are also common. “Lift slabs” are all precast at ground level around the columns and lifted to their final position.

In flat-slab frames subjected to lateral loading, strips of the flat slab between the columns act and behave as beams. The effective width of such strips increases with increasing seismic demands but is quite uncertain. Regardless of this uncertainty, the stiffness and flexural capacity of the strips is relatively low compared to those of columns, conducive to a beam mechanism with column plastic hinging only at the base, as in strong-column-weak-beam designs. Owing to the flexibility of the flat slab, flat-slab frames may develop large second-order ($P-\Delta$) effects. There is also large uncertainty about the behavior of the region of the slab around the column under inelastic cyclic loading, and especially about its capacity to transfer to the column the floor gravity loads through vertical shear stresses, along with the slab moment due to the cyclic lateral loading. Experimental work on slab-column connections subjected to large amplitude cyclic deformations suggests that slab-column connections having a large safety margin against punching shear failure under the concurrent gravity loads can sustain without failing significant cyclic deformation demands (Fardis 2009).

According to currently accepted conventional wisdom, beamless frames of columns and flat slabs (“flat-slab frames”) are not considered suitable for earthquake resistance, owing to questions about their lateral displacement capacity. Indeed, buildings with “flat-slab frame” systems suffered heavy damage in the Northridge (1994) earthquake. However, in earthquakes that have inflicted heavy damage to urban centers in Europe, such buildings either performed fairly well, despite the lack of proper design and detailing for earthquake resistance, or were damaged in the vertical elements supporting the flat slab, but not at the connection. So, the statement that “flat-slab frames” are doomed in strong earthquakes is inconclusive. Nevertheless, owing to the gaps in knowledge mentioned above, modern seismic design codes do not have rules for the design and detailing of flat slabs as part of a ductile lateral-load-resisting system.

Precast Concrete Systems

Introduction

As pointed out in section “[Introduction](#),” the connections between precast elements are points of discontinuity in the flow of inertia forces from the masses to the ground: they may fail, either by failure of the joining element itself or due to damage of the concrete around the fastenings of this element. Depending on their connections, earthquake-resistant systems of precast elements:

1. Emulate monolithic construction, with a continuous and smooth force path, or
2. Are designed to safely accommodate the seismic displacements in connections which are weaker than the precast elements they connect (“jointed” systems)

Emulation of Monolithic Construction

Seismic design codes typically address only precast systems emulating monolithic construction, granting to them the same strength and ductility as those of geometrically similar cast-in-place structures.

The connections between the elements belong to one of the following types (fib [2003](#)):

1. Energy-dissipating ductile connections, based on yielding of those longitudinal bars of the elements which enter the connection and flexural plastic hinging at the end of the connected element as in cast-in-place construction; the connection and the connected elements follow the same code rules as in monolithic construction.
2. Overdesigned (“strong”) connections, capacity-designed to remain elastic while flexural yielding occurs at another location in the element, away from the connection.

“Jointed” Precast Systems

This type of construction is not covered in prescriptive seismic design codes. Some codes allow, though, experimental demonstration of “energy-dissipating connections” not complying with the prescriptive rules for precast or cast-in-place structures.

“Jointed” systems normally employ “dry connections” formed by welding or bolting reinforcing bars or steel embedments and dry packing or grouting. Inelastic seismic deformations do not take place in flexural plastic hinges in the connected elements, but at their interfaces, which continuously open and close during the earthquake.

A common example is tilt-up construction of precast walls, normally designed to remain essentially elastic in an earthquake.

Less common are innovative systems, which employ at the connections unbonded or partially bonded post-tensioning tendons alongside non-prestressed longitudinal bars and allow the whole structure to rock with respect to the ground, or its components to rock in a stable manner relative to each other as rigid bodies. Sometimes supplemental energy dissipation is added to reduce the displacement response. Such systems were proposed and tested in the end of the last century (Nakaki et al. [1999](#)). They comprise:

- Frames of precast concrete beams connected “dry” to precast columns via concentric unbonded post-tensioned strands, continuous through the joint
- Precast concrete walls, connected “dry” to the foundation via vertical concentric unbonded tendons

Such systems were applied during the first decade of the century in high seismicity areas: San Domingo (Stanton et al. [2003](#)), San Francisco (Englekirk [2002](#)), and Christchurch (where a building with this system survived unscathed the 2011 earthquake). However, the robustness of the system against progressive collapse under accidental extreme events should be demonstrated as well.

Floor Diaphragms

At any horizontal level where significant masses are concentrated, the vertical elements of the lateral-force-resisting system should be connected through floor diaphragms, transferring

the inertia forces from the masses to the lateral-load-resisting system and tying it together into an integral whole. The diaphragms should be designed to remain elastic while performing this in-plane action, alongside the out-of-plane flexure resisting the floor gravity loads and transferring them to the vertical elements.

Normally a cast-in-place solid slab qualifies as a diaphragm, if it is monolithically connected to the elements of the lateral-force-resisting system and has thickness and two-way reinforcement which meet the requirements of design codes concerning the flexural strength under factored gravity loads, the limits on deflection and crack width under service loads, and the minimum slab reinforcement.

In a floor incorporating precast elements, the in-plane shear transfer at the joints between these elements is questionable; it is strongly recommended to rely only on a cast-in-plane RC topping – for which Eurocode 8 (CEN 2004) requires at least 50 mm of thickness and the minimum slab reinforcement in both horizontal directions. The topping should be cast over a clean, very rough substrate; otherwise, shear connectors to the precast floor elements should be provided. If there is no topping meeting all these requirements, the joints between precast elements should be crossed by reinforcement capable of transferring the in-plane forces of the diaphragm.

Cases requiring special attention – and possibly verification of the diaphragm by calculation – include:

- Diaphragms with irregular geometry in plan, recesses and reentrances, irregular and large openings, etc.
- Irregular in-plan distribution of the masses and/or of the stiffness of the lateral-force-resisting system (e.g., with set-backs or offsets, vertical elements terminating below the top level, etc.)
- The roof of a basement with RC walls along only a part of the perimeter or of the ground floor area
- Cast-in-place waffle slabs with a thin, lightly reinforced top slab.

Shallow Foundation Systems

Introduction

In modern construction, the foundation system is practically always made of concrete, even when the superstructure is built of another material.

The term “shallow foundation” covers systems of isolated footings (pads) and tie-beams, foundation-beams, and rafts. The same types of foundations are often called “spread foundations.” Deep foundations, through piles, are not commonly used in buildings and are not treated here.

The role of the foundation is to transfer the gravity loads from the vertical members of the structure to the ground. So the natural choice for the foundation of a concrete column is to widen its base in order to adapt the section area, through which the vertical load passes, to the ground bearing capacity – lower than that of the concrete section. Each one of the resulting footings – normally concentric and square – is often connected to neighboring ones via horizontal tie-beams of rectangular section. The main role of tie-beams is to reduce the magnitude and impact of differential settlements of adjacent footings, due to large imbalances between their vertical loads and/or variations in the underlying soil. If a more interconnected foundation is essential, instead of placing a number of tie-beams and isolated footings in a row, a foundation beam is used: a deep beam with an inverted-T or L section, which transfers, through the underside of its bottom flange, vertical loads to the ground all along its length, not just around the column base. If the overall weight of the building and its contents is so large that the soil bearing capacity needs to be mobilized over most of its footprint area, it is normally cost-effective to combine all foundation elements in a raft, which acts as a single footing under the entire building, transferring vertical loads to the ground throughout its plan area.

Therefore, there are three types of shallow foundation systems for buildings, listed below

in ascending order of cost and effectiveness in transferring the gravity loads to the soil:

1. Isolated footings, with tie-beams (Figs. 1a and 2a) or without
2. (Two-way) Foundation beams (Figs. 1b and 2b)
3. Foundation rafts

Isolated Footings and Tie-Beams

If the building is subjected to significant seismic lateral loads, the foundation elements should be designed to transfer to the ground the large bending moments which develop at the base of each vertical element, as well as the action effects of the overall overturning moment due to the lateral loads, notably the uplifting of the “windward” side of the building and the additional vertical compression at the “leeward” side. In isolated footings, the vertical force that the footing must transfer to the ground acts at a large eccentricity (i.e., moment-to-vertical-force ratio) with respect to the center of the footing’s underside, especially when the vertical force due to the overall overturning moment is tensile. To accommodate this eccentricity, footings may have to be large in plan. To reduce the eccentricity, stiff tie-beams may connect every footing with the adjacent ones in both horizontal directions. The bending moments (in counterflexure) and the shears in tie-beams always have a sense of action that leads to a reduced moment reaction of the ground at the underside of the footing. So, for given moments and forces applied at the top of the footing by the vertical element, the larger the stiffness of the tie-beams, the smaller this moment reaction is at the base of the footing.

Tie-beams should be connected directly to the body of the footing in order to:

- Avoid creating a squat column between the soffit of the beam and the top of the footing
- Increase the effectiveness of tie-beams, by increasing their stiffness, EI/L_{cl} , through the reduction of their clear length, L_{cl} .

Tie-beams have another important role in design against lateral loads: to prevent differential horizontal slippage of footings, a role which may be played also by a horizontal slab between them (not integral to them).

Two-Way Systems of Foundation Beams

It is clear from Section “Isolated Footings and Tie-beams” that isolated footings may not be cost-effective for an earthquake-resistant building, even on competent ground. If the tie-beams have to be very deep and stiff to alleviate the eccentricity problem of footings, they may as well be merged with them into a foundation beam. That beam will work over its entire length as a single integral member, absorbing into its own bending moment diagram, the bending moments applied at its top flange by the columns. Thanks to its long overall length, it transfers efficiently to the ground the overall overturning moment applied to the beam by the columns it supports, with very little uplift of its windward end. So, especially for high seismicity, a two-way system of foundation beams, supporting all vertical elements of the building throughout the plan of the foundation, is the system of choice, especially for a tall building, regardless of the competence of the soil. It is also more cost-effective.

Perimeter frames are often stiffer than interior ones; sometimes they include walls. So they resist a larger share of the seismic action, while, owing to their smaller tributary area, they support a smaller fraction of the gravity loads. So their foundation may be more challenging than that for interior vertical elements. If the perimeter frames include walls, they may need deep foundation beams to prevent differential rocking of the walls at the base (Fig. 2). If there is a basement, the perimeter foundation beams can extend up to its top slab, at least along most of the length of each side of the perimeter. In that case, the building can be provided with the most effective foundation system for earthquake resistance, namely, the box system described in the next section.

Unlike two-way foundation beams, a foundation raft does not offer additional advantages for seismic design. Moreover, its analysis and design

are demanding even for gravity loads: the raft should be discretised with a fairly fine mesh of plate finite elements, each node being supported on the soil through a vertical Winkler spring. So, there is no special reason to choose a raft over a two-way system of foundation beams for purposes of earthquake resistance.

Box-Type Foundation Systems

The ideal shallow foundation for earthquake-resistant buildings is a box system, consisting of (Fardis et al. 2005):

1. Wall-like deep foundation beams along the entire perimeter of the foundation, possibly supplemented with interior ones across the full length of the foundation system. These deep beams are the main foundation elements transferring the seismic action effects to the ground. In buildings with a basement, the perimeter foundation beams may also serve as basement perimeter walls.
2. A concrete slab at the level of the top flange of the perimeter foundation beams (playing the role of the roof of the basement, if there is one), acting as a rigid diaphragm.
3. A foundation slab, or a grillage of tie-beams or foundation beams, at the lowest level of the perimeter foundation beams.

Such a system suits well buildings with basement(s), even those only partially embedded and/or with some openings along the perimeter. However, for the system to be fully effective, any openings between the top of the perimeter foundation beam and the soffit of the beam supporting the basement roof should be limited to a small fraction of the corresponding side of the perimeter.

If their perimeter foundation beam is deep enough to accommodate a basement story, the foundation system of the examples in Fig. 2 may be turned into a box type one by adding a slab at the top level of the foundation beams.

It is not essential to have a raft or a two-way system of foundation beams as in Fig. 2b at the lowest level of the deep foundation beams along the perimeter. Interior vertical elements may be

founded instead on individual footings, provided that the footings are connected to the bottom of the perimeter foundation beams through a diaphragm consisting of two-way tie-beams (as in Fig. 2a) or a slab (possibly serving also as the basement floor). As the transfer of the full seismic action from the ground to the superstructure (or vice versa) takes place through the perimeter beams, the foundation of interior elements and the abovementioned diaphragm may be at a level slightly above the bottom of the perimeter beams.

Owing to its large rigidity and strength, a box-type foundation works as a rigid body. Thus, it minimizes uncertainties about the distribution of seismic action effects over the interface between the ground and the foundation system and imposes the same rotation of all vertical elements at the level of their connection with this system, so that they may be considered as fixed there against rotation. Plastic hinges in walls and columns will develop just above the top of the box-type foundation. Fixity of interior vertical elements at the top of the foundation system is achieved through a couple of horizontal forces that develop at the levels of the top and bottom of this system. The main role of the diaphragm at the lowest level of the perimeter foundation beams is to provide the lower-level horizontal force for the fixity of vertical elements at the top of the foundation box.

The large rigidity and strength of a box-type foundation system protects the interior columns within the box and all its beams (including those at the roof of the basement) from high seismic moments and shears (see Fig. 9d, e) and from plastic hinging (except possibly at the column tops underneath the roof of the basement). However, interior walls develop large and, as a matter of fact, reverse seismic shears within the basement (see Fig. 9a, c), which makes their shear design challenging.

The seismic bending moment at the connection of interior vertical elements with their foundation element is small, and a footing (subjected in this case to essentially concentric compression) is sufficient for each one of them (see Fig. 9a, b, d).

The top slab of a box-type foundation transfers the seismic shears from the interior vertical elements to the perimeter wall-type foundation beams. It should have sufficient in-plane stiffness (i.e., thickness) and strength (two-way reinforcement) and should be free of large interior openings. The restraint of shrinkage of this slab by the stiff perimeter elements may induce through thickness cracking. Two-way reinforcement at both surfaces of the slab will reduce the consequences of such cracking on its in-plane stiffness. If the slab is cast shortly after the perimeter elements of the box to minimize their differential shrinkage, cracking due to the restraint of drying shrinkage is less likely. Another option is to lap-splice all slab reinforcement in each direction of the slab along a strip, all the way from one side of the perimeter to the opposite, and defer for a few days casting of the concrete in that strip and striking of the formwork of the entire slab. In this way, the early (and largest) part of the ultimate drying shrinkage of the parts of the slab cast first takes place without any restraint.

A box-type foundation offers additional advantages, not captured by conventional analysis of the seismic response (Fardis 2009):

- An integral rigid foundation for the whole building filters out differences in the seismic input between different points of the base, due to arrival there of the seismic waves with a time-lag and other minor differences. So it introduces in the superstructure a single seismic excitation, which at any given point in time is the average of the ground motion over the entire interface (horizontal and vertical) between the foundation system and the ground. This smoothing of the input motion removes high-frequency components. The larger the interface between the ground and an integral foundation (e.g., in buildings with a raft at the bottom or with deep embedment due to more than one basement stories), the more extensive the smoothing of the input motion.
- If the system of the foundation and the superstructure is stiff relative to the underlying soil stratum (more specifically, if its fundamental

period is shorter than that of the soil deposit) and, moreover, there is an integral and rigid foundation system for the entire building, some of the input energy, instead of being trapped within the building, is radiated back into the ground (“radiation damping”), reducing the seismic forces and deformations in the superstructure.

- In the extremely rare, but not inconceivable, case of surface faulting through the foundation (which happened at the Awaji island in Kobe, 1995, and at the Bolu viaduct in the Duzce, 1999, earthquake), an integral and rigid foundation may straddle the fault without collapse or severe damage in the superstructure due to the fault displacements – horizontal or vertical.

Summary

Earthquake-resistant concrete structures are typically cast in situ: monolithic construction suits best the nature of concrete as a material and helps ensure a smooth and continuous force path, which is essential for earthquake resistance. To serve this goal, precast concrete systems typically emulate monolithic connections; otherwise, they are designed to accommodate at the joints differential seismic displacements between the connected elements. Beam-column frames are very reliable for resistance to strong earthquake through energy dissipation and ductility; concrete walls are cost-effective for earthquake resistance and offer, through their stiffness, protection from damage under smaller or moderate earthquakes. “Dual” earthquake-resistant systems combine frames and walls and their advantages but are more challenging for a sound seismic design. Flat-slab frames are not trusted to resist the earthquake alone, because of their lateral flexibility and insufficient knowledge concerning the behavior of slab-column connections. Two-way foundation beams are much more efficient for earthquake-resistant construction than isolated footings, be it with two-way tie-beams; a box-type foundation is the best for that purpose but suits more buildings with basement(s).

Notation of Symbols

- B** Horizontal dimension of footing
 b_w Width of cross section
 h Depth of cross section
 H_{tot} Wall height
 l_w Wall length
 L_s Shear span (=M/V ratio)
 M Bending moment
 N Axial force in a vertical member
 V Shear force
 $\mu \equiv M/(bh^2f_c)$ Nondimensional bending moment
 $\nu = N/(bhf_c)$ Nondimensional axial force in a vertical member

Introduction

Failures in structural systems subjected to random dynamic loadings can be classified essentially into two broad categories. Failures that occur when the structure response exceeds safe threshold limits during its service life are due to overloading and are deemed to occur at the instant when the response crosses the threshold for the first time. These failures are known as first passage failures (Nigam 1983; Lin 1967). The alternative mode of failure in vibrating system occurs when the accumulated damage in the structure reaches a threshold limit due to the gradual degradation in the structure material on account of fatigue. It is obvious that for random loadings, both the first passage time and the

fatigue damage are random quantities and a reliability analysis of the structure against these modes of failure requires characterization of these quantities.

Reliability analysis of structures against random dynamic loadings is a problem in time-variant reliability analysis. Adopting a probabilistic approach provides a rationale framework within which the uncertainties in the loading and in the structure response can be adequately handled leading to quantification of the failure probability of the structure. In this approach, the random dynamic loads are typically modeled as stochastic processes. Consequently, the structure responses are also stochastic processes whose probabilistic characteristics are different from that of the loading. Here, the structure which behaves as a filter to the excitations significantly alters the probabilistic characteristics of the uncertainties associated with the loadings. Typically, the structure response can be viewed as a nonlinear transformation of the loading and are random processes in time. Time-variant reliability analysis of the structures requires characterization of the response processes.

When the structure response is a stochastic process, the time when the response exceeds the safe limits or when the total accumulated damage reaches a critical threshold are random quantities, quantification of which can be carried out using theories of probability and stochastic processes. The crux in estimating either the first passage failure probabilities or the random fatigue damage lies in evaluating the crossing statistics of the response using the well-known Rice's integral (Rice 1944). This requires estimating the joint probability density function of the response and its instantaneous time derivative. This, however, is not easy as even for Gaussian loadings the response of nonlinear structures is non-Gaussian whose marginal probability density function (pdf) itself is difficult to estimate.

First Passage Failures

Estimating the first passage failures in randomly vibrating structures requires estimating the probability of exceedance of the structure response for

the first time within the specified time duration. Let $Y(t)$ be the response of a randomly vibrating structural system; see Fig. 1. Let the dotted line be the safe threshold level the crossing of which constitutes a failure due to overloading. The time at which the first crossing of the response across the threshold level from below is defined as the first passage time, denoted by T_f . Clearly, for a random time history $Y(t)$, T_f is a random variable. If no failure is deemed to occur within the time period of interest, T , it implies that $Y(t)$ lies below the threshold α for all time t . Therefore, the mathematical statement for the failure probability against overloading can be expressed as

$$P_f = 1 - P[Y(t) \leq \alpha; \forall t \in (t_0, t_0 + T)], \quad (1)$$

where, t_0 is initial time, T is the duration, α is the safe threshold limit, P_f is failure probability, and $P[\cdot]$ is probability measure. Mathematical evaluation of P_f from Eq. 1 demands the knowledge of the infinite dimensional probability density function of $Y(t)$ which is an impossibility.

Alternatively, Eq. 1 can be written in the time invariant format by introducing a variable Y_m , as (Melchers 1999)

$$P_f = 1 - P[Y_m \leq \alpha] = 1 - P_{Y_m}(\alpha), \quad (2)$$

where, Y_m is the extreme value of the process $Y(t)$ given by

$$Y_m = \max_{t_0 \leq t \leq t_0 + T} \{Y(t)\}$$

and $P_{Y_m}(\alpha)$ is the probability distribution function (PDF) of Y_m and is referred to as the extreme value distribution (EVD) for the process $Y(t)$ in time duration T . If the threshold levels are sufficiently high, such that, the crossings can be assumed to be rare and independent, the crossings can be modeled as a Poisson counting process. Under these assumptions, it can be shown that the EVD can be approximated as (Cramer 1966),

$$P_{Y_m}(\alpha) = \exp \left[- \int_0^T \int_0^\infty \dot{y} p_{Y\dot{Y}}(\alpha, \dot{y}, t) \dot{y} d\dot{y} dt \right]. \quad (3)$$

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,
Fig. 1 Schematic diagram of first passage failure

Here, $p_{Y\dot{Y}}(\alpha, \dot{y}, t)$ is the joint transitional probability density function of the process and its instantaneous time derivative. It can be shown that for stationary processes $Y(t)$, Eq. 3 can be expressed in the simpler form

$$P_{Y_m}(\alpha) = \exp[-v_Y(\alpha)T], \quad (4)$$

where, $v_Y(\alpha)$ is the mean upcrossing intensity of the process $Y(t)$ across level α . The expression for estimating the mean crossing intensity $v_Y(\alpha)$ for a stationary process $Y(t)$ is available from Rice's formula (Rice 1944) and is given by

$$v_Y(\alpha) = \int_0^\infty \dot{y} p_{Y\dot{Y}}(\alpha, \dot{y}) d\dot{y}. \quad (5)$$

Here, $p_{Y\dot{Y}}(\cdot, \cdot)$ denotes the joint stationary pdf of the process $Y(t)$ and its instantaneous time derivative $\dot{Y}(t)$.

It must be noted here that the expression for the extreme value distribution in terms of the mean crossing intensity given in Eq. 4 is approximate whose quality depends on the accuracy of the assumptions of the level crossings being Poisson. Thus, as the levels become higher, the crossings become rarer and satisfy the assumptions of a Poisson counting process. Thus, at high levels α , Eq. 4 approaches the exact value. However, for lower levels of α , the quality of the approximation deteriorates as the assumptions

of a Poisson counting process are not met. Thus, the estimates of the failure probability based on the extreme value distributions are more accurate at the tails of the distribution. However, irrespective of the level α , the expression for the mean crossing intensity, given by Eq. 5, is always exact.

Random Fatigue Damage

For random response $Y(t)$ in a vibrating system, the accumulated linear fatigue damage due to $Y(t)$ is denoted by D_T and is given by

$$D_T = \sum_{j=1}^{Y(t)} \frac{1}{N(u, v)} \quad (6)$$

where, $N(u, v)$ denotes the strength of the structure material and is equal to the number of constant amplitude cycles, with amplitude range (u, v) that lead to fatigue. Usually,

$$N(u, v) = \frac{1}{f(u, v)} = \frac{1}{k(v - u)^a}, \quad (7)$$

where, k and $a \geq 1$ are material constants. Clearly, if $Y(t)$ is a random process, the stress amplitude ranges defined by (u, v) pair are random and obviously D_T is a random variable. For complete characterization of the random fatigue damage, one needs to characterize the pdf of D_T . This is, however, a difficult task. A simpler approach to

characterization of the random variable D_T would be to estimate its first moment, defined as $E[D_T]$ where, $E[\cdot]$ is the expectation operator.

Estimates of the mean fatigue damage can be carried out in the time domain using Monte Carlo simulations. This would imply simulation of a large ensemble of random time histories for $Y(t)$, evaluating D_T corresponding to each time history and taking their mean. This is however computationally too expensive, especially as fatigue damage is a gradual degradation mechanism and would require simulations of very long time histories of $Y(t)$. However, an alternative spectral approach for approximating the expected fatigue damage has been discussed in the literature. This is discussed next.

Assuming rainflow cycle counting, it can be shown that the expected fatigue damage is given by Rychlik (1993)

$$E[D_T] = T \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f_{12}(u, v) \mu(u, v) du dv, \quad (8)$$

where, $\mu(u, v)$ is known as the intensity of interval upcrossings, $E[\cdot]$ is the expectation operator, and $f_{12}(\cdot)$ is the second derivative of a function related to the damage accumulation rule. Estimating $\mu(u, v)$ is however a very difficult task. An easier option would be to estimate the bounds for intensity crossings. It can be shown that (Rychlik 1993)

$$\mu(u, v) \leq \min[\mu(u, u), \mu(v, v)] = \hat{\mu}(u, v), \quad (9)$$

where, $\mu(u, u) = \mu(u)$. The mean crossing rate $\mu(u)$ can be easily computed using the Rice's formula given in Eq. 5.

Difficulties in Estimating the Mean Crossing Intensity

The discussion in this section shows that the mean crossing intensity plays a crucial role in estimating the failure probability of vibrating structures, irrespective of the failure being defined in terms of first passage failures or random fatigue failures. The numerical evaluation of Rice's integral does not pose much challenge, even if the integral cannot be evaluated

analytically. However, the crux here lies in the knowledge of the joint pdf $p_{Y\dot{Y}}(\cdot, \cdot)$. For structural response which can be modeled as Gaussian, $Y(t)$ is Gaussian as well as its instantaneous time derivative. In such situations, $p_{Y\dot{Y}}(\cdot, \cdot)$ can be exactly obtained, which enables an analytical representation of $v_Y(x)$. However, it must be noted that $Y(t)$ is the structure response when subjected to random loadings, say $X(t)$. Thus, mathematically, one can write

$$Y(t) = g[X(t)], \quad (10)$$

where, the function $g[\cdot]$ behaves like a filter and depends on the structure behavior. Clearly, if $X(t)$ is Gaussian and $g[\cdot]$ is linear, $Y(t)$ is a Gaussian process. However, usually $g[\cdot]$ is nonlinear. In these situations, even if $X(t)$ is Gaussian, $Y(t)$ is non-Gaussian whose marginal pdf $p_Y(y, t)$ is itself difficult to estimate. Estimating the joint pdf $p_{Y\dot{Y}}(\cdot, \cdot)$ is an even harder task. This poses serious challenges in estimating the crossing statistics, and in turn, the failure probabilities against overloading or fatigue.

Studies exist in the literature which have focused on developing approximations for the joint pdf $p_{Y\dot{Y}}(\cdot, \cdot)$, especially when $X(t)$ is a Gaussian scalar or a vector process and $g[\cdot]$ is a quadratic transformation. In this entry, a methodology is presented by which one can derive analytical/numerical approximations for the crossing statistics of the response of nonlinear structures subjected to random vibrations, using a spectral approach. This involves transforming the problem into a mathematical subspace spanned by the basis vectors obtained from the projections of the spectral content of the input process. The basis functions are obtained from a Karhunen-Loève representation of the stochastic loading. Subsequently, the response is obtained as a polynomial chaos expansion in the same basis space. Finally, quantification of the probabilistic characteristics of the response are obtained.

The primary focus of this discussion is on the use of numerical algorithms when polynomial chaos expansion (PCE) based representation of the response is sought. After a brief introduction to polynomial chaos expansion, discussions focus

on the use of three methods that are used in representing the response using PCE. These include the stochastic Galerkin method, the stochastic collocation technique, and, finally, the sparse grid approach using Smolyak's algorithm. A comparative study is presented on the efficiency of these methods. Finally, the estimates of the failure probability are obtained against first passage failures and against random fatigue. The predictions obtained from PCE have been validated using full-scale Monte Carlo Simulations. The methodology has been demonstrated through a numerical example of obtaining the response of a vibrating 2-D airfoil subjected to gusty wind flow regime.

Karhunen-Loève Expansion

According to the Karhunen-Loève (K-L) theorem, a stochastic process on a bounded interval can be represented as an infinite linear combination of orthogonal functions, the coefficients of which constitute uncorrelated random variables. The basis functions in K-L expansions are obtained by eigendecomposition of the autocovariance function of the stochastic process and are shown to be its most optimal series representation. The deterministic basis functions, which are orthonormal, are the eigenfunctions of the autocovariance function and their magnitudes are the eigenvalues. The Karhunen-Loève expansion converges in the mean-square sense for any distribution of the stochastic process (Papoulis and Pillai 2002). A K-L representation of a zero-mean stochastic process $f(t, \theta)$ can be represented in the form

$$f(t, \theta) = \sum_{i=0}^{\infty} \xi_i(\theta) \sqrt{\lambda_i} \phi_i(t), \quad (11)$$

where, the coefficients λ_i and the functions $\phi_i(t)$ respectively are the eigenvalues and the eigenfunctions of the covariance function of the process, denoted by $R_{ff}(t, s)$, and are evaluated by solving the Fredholm integral equation of the second kind, given by

$$\int_0^T R_{ff}(t, s) \phi_i(s) ds = \lambda_i \phi_i(t). \quad (12)$$

Here, the parameter t indicates time and θ represents the random dimension. Note that the autocorrelation function $R_{ff}(t, s)$ need not be stationary. In Eq. 11, $\{\xi_i(\theta)\}$ is a vector consisting of uncorrelated random variables with zero mean and unit variance. Since $\phi_i(t)$ are eigenfunctions, it is obvious that

$$\int_0^T \phi_i(t) \phi_j(t) dt = \delta_{ij}, \quad (13)$$

where, δ_{ij} is the Kronecker-delta function. This implies that $\{\phi_i(t)\}$ constitute a set of orthonormal vectors and can be viewed as basis vectors.

Since Eq.11 is an infinite series, it becomes imperative to decide on the number of terms to be retained in the expansion of $f(t, \theta)$. It is seen that not all terms have a significant contribution in the expansion. If the series expansion is truncated after N terms, then

$$\tilde{f}(t, \theta) = \sum_{i=0}^N \xi_i(\theta) \sqrt{\lambda_i} \phi_i(t), \quad (14)$$

is the approximate representation for the process $f(t, \theta)$. The truncation error can be expressed as

$$e_N(t) = f(t, \theta) - \tilde{f}(t, \theta) = \sum_{j=N+1}^{\infty} \xi_j(\theta) \sqrt{\lambda_j} \phi_j(t) \quad (15)$$

and represents the remainder of the series after truncation. The mean square error due to truncation, for the entire time duration $[0, T]$ is given by

$$\begin{aligned} E \left[\left\{ \int_0^T e_N(t) dt \right\}^2 \right] &= \sum_{j=N+1}^{\infty} \sum_{k=N+1}^{\infty} E \left[\xi_j(\theta) \xi_k(\theta) \right] \\ &\quad \sqrt{\lambda_j} \sqrt{\lambda_k} \int_0^T \int_0^T \phi_j(t_1) \phi_k(t_2) dt_1 dt_2 \\ &= \sum_{j=N+1}^{\infty} E \left[\xi_j(\theta)^2 \right] \lambda_j \int_0^T \phi_j^2(t) dt \\ &= \sum_{j=N+1}^{\infty} \lambda_j. \end{aligned} \quad (16)$$

The simplifications in Eq. 16 follows from the property of the random variables $\xi(\theta)$ and Eq. 14. The result from Eq. 16 implies that the accuracy of the K-L approximation can be analyzed by studying the eigenvalues $\{\lambda_j\}$ obtained by solving Eq. 12. Typically, N is chosen such that the mean square error is less than a tolerance value ϵ_{tol} , usually taken to be of 10^{-3} or less.

For numerical calculations, the autocorrelation function $R_{ff}(t, s)$ is usually estimated from measurement data and are available only in discrete form as a matrix $\mathbf{R}$. It can be shown that the integral equation in Eq. 12 can be expressed in the matrix form as

$$\mathbf{R}\phi^T = \lambda\phi^T. \quad (17)$$

Thus, the integral equation in Eq. 12 is now expressed as an eigenvalue problem, where λ are the eigenvalues having the same meaning as in Eq. 12 and ϕ represents the eigenfunction in discrete form spanning the length $[0, T]$. It is obvious that the orthogonality conditions in Eq. 14 are satisfied.

The simulation of a random process using K-L expansion can now be summarized in the following algorithmic steps:

1. Generate the covariance matrix $\mathbf{R}$ from the autocovariance function of the random process. Let the dimension of $\mathbf{R}$ be $k \times k$
2. Solve the eigenvalue problem given by Eq. 17 and evaluate the k eigenvalues and eigenfunctions
3. Decide the number of terms N to be included in the series expansion based on the magnitude of eigenvalues, such that the mean square truncation error $\sum_{j=N+1}^k \lambda_j < \epsilon_{\text{tol}}$, where ϵ_{tol} is a specified tolerance value
4. Generate a set of standard normal random variables $\xi(\theta)$
5. Substitute the corresponding eigenvalues, eigenfunctions, and random variables in Eq. 15 to obtain realizations of the random process

It must be remarked here that there are alternative methods for simulating stationary Gaussian processes. Of these, the most commonly used

is the spectral representation proposed by (Shinozuka and Jan 1972). However, the advantage of using the K-L expansions for modeling the input excitations to nonlinear problems become evident when the response is obtained in terms of the basis vectors $\phi(t)$ that have been used for the K-L expansions. This is achieved by using polynomial chaos. This is discussed in the following section.

Polynomial Chaos Expansion

Since the KL expansion is obtained as a linear sum of Gaussian random variables, the series can be used to represent only Gaussian random processes. For spectral representation of non-Gaussian random processes, one uses the more general form known as the polynomial chaos expansion. Polynomial chaos expansion is a spectral representation of the random process in terms of orthonormal basis functions and deterministic coefficients. Based on the Cameron and Martin theorem (Cameron and Martin 1947), it can be shown that a zero mean, second order random process can be represented as

$$\begin{aligned} X(t, \theta) = & \hat{x}_0 \Gamma_0 + \sum_{i_1=1}^{\infty} \hat{x}_{i_1} \Gamma_1(\xi_{i_1}(\theta)) \\ & + \sum_{i_1=1}^{\infty} \sum_{i_2=2}^{\infty} \hat{x}_{i_1 i_2} \Gamma_2(\xi_{i_1}(\theta), \xi_{i_2}(\theta)) + \dots, \end{aligned} \quad (18)$$

where, $\{\Gamma_n(\xi_{i_1}, \xi_{i_2}, \dots, \xi_{i_n})\}$ are the orthogonal basis functions and $\{\hat{x}_0, \hat{x}_{i_1}, \hat{x}_{i_1 i_2}\}$ are the corresponding projections. Moreover, the orthogonal basis functions are assumed to be polynomial functions of standard Gaussian random variables $\xi = (\xi_{i_1}, \xi_{i_2}, \dots, \xi_{i_n})$. This is the reason for the terminology ‘‘polynomial chaos expansions.’’ Equation 18 is usually written in the more compact form

$$X(t, \theta) = \sum_{i=0}^{\infty} x_i(t) \Psi_i(\xi(\theta)), \quad (19)$$

where, Ψ_i denotes the basis functions and $x_i(t)$ are the deterministic projections along these basis functions. Since Ψ_i 's are the basis functions, they are mutually orthogonal and satisfy the following identity

$$\langle \Psi_i \Psi_j \rangle = \langle \Psi_i^2 \rangle \delta_{ij}, \quad (20)$$

where, δ_{ij} is the Kronecker delta function and $\langle \cdot \rangle$ is the expectation operator of the form

$$\langle x \rangle = \int_{\Omega} x w(x) dx. \quad (21)$$

Here, $w(x)$ is an appropriate weighting function and Ω is the integration domain. Truncating Eq. 19 to p terms, $X(t, \theta)$ can be approximated as

$$X(t, \theta) = \sum_{i=0}^p x_i(t) \Psi_i(\xi(\theta)). \quad (22)$$

The number of terms up to which the series is truncated, p , is known as the order of expansion. For n number of random variables and polynomial order n_p , p is given by the following:

$$p = \frac{(n + n_p)!}{n! n_p!} - 1. \quad (23)$$

The use of PCE to represent the solution of a nonlinear differential equation is discussed next.

Response Analysis Using Polynomial Chaos Expansion

Let us consider a differential equation of the form

$$\ddot{x} + f(x, \dot{x}) = g(t), \quad (24)$$

where, $g(t)$ is a Gaussian random process, expressed as a K-L expansion

$$g(t, \theta) = \sum_{i=0}^{\infty} \xi_i(\theta) \sqrt{\lambda_i} \phi_i(t). \quad (25)$$

Since the differential equation is nonlinear, it is clear that $x(t)$ is a non-Gaussian random process.

Now, let us assume that $x(t)$ can be represented as a PCE. Thus, Eq. 24 can now be written as

$$\begin{aligned} \sum_{i=0}^p \ddot{x}_i(t) \Psi_i(\xi) + f \left(\sum_{i=0}^p x_i(t) \Psi_i(\xi), \sum_{i=0}^p \dot{x}_i(t) \Psi_i(\xi) \right) \\ = \sum_{i=0}^M \xi_i \sqrt{\lambda_i} \phi_i(t), \end{aligned} \quad (26)$$

where, the basis functions $\Psi_i(\xi(\theta))$ are known but the coefficients $\{x_i\}$ are to be determined. Some of the techniques by which these deterministic coefficients can be determined are discussed in the subsequent sections.

Stochastic Galerkin Method

In Galerkin PC approach, the chaos expansion of the system response is substituted into the governing equations leading to a set of coupled equations in terms of the chaos coefficients

$$\begin{aligned} \langle \Psi_k^2 \rangle \ddot{x}_k(t) + \left\langle f \left(\sum_{i=0}^p x_i(t) \Psi_i, \sum_{i=0}^p \dot{x}_i(t) \Psi_i \right) \cdot \Psi_k \right\rangle \\ = \sum_{j=0}^M \langle \xi_j \cdot \Psi_k(\xi) \rangle \sqrt{\lambda_j} \phi_j(t), \end{aligned} \quad (27)$$

where, $k = 0, 1, 2, \dots, p$. These coupled deterministic equations typically have terms, such as, $E[\Psi_i(\xi) \Psi_j(\xi) \dots \Psi_k(\xi)]$ as coefficients. These coefficients represent multidimensional integrals of the form

$$E[\Psi_i(\xi) \Psi_j(\xi) \dots \Psi_k(\xi)] = \int \dots \int \psi_i \dots \psi_k p_{\xi}(\xi) d\xi \quad (28)$$

and need to be evaluated *a priori*.

For nonlinear dynamical systems, the form of these coupled deterministic equations are usually complicated and their solution can be tedious and time consuming. Depending on the nonlinearity, the number of terms in these expectations could be large. Evaluation of these terms imply multidimensional integration and need to be carried out prior to the solution of the coupled

deterministic equations. It must be noted that the application of the stochastic Galerkin method changes the form of the differential equations that need to be solved. Hence, the stochastic Galerkin method is referred to as an intrusive method. In order to circumvent these difficulties, several alternative methods are available in literature. Some of these are discussed in the subsequent sections.

Stochastic Collocation Method

The method of stochastic collocation is an efficient way that has been discussed in the literature (Ghanem and Spanos 1991; Desai and Sarkar 2010) for obtaining the PCE projections x_j . In contrast to the Galerkin method, the polynomial chaos expansions are not substituted in the governing equation and hence it is known as nonintrusive. Instead, here one uses the property that $\langle \Psi_i, \Psi_j \rangle = 0$ for $i \neq j$ for estimating the coefficients x_j . This involves multiplying both sides of Eq. 19 by Ψ_j and taking expectations. This leads to an estimate of $x_j(t)$ from the following formula

$$x_j(t) = \frac{\langle X(t, \xi(\theta)), \Psi_j \rangle}{\langle \Psi_j^2 \rangle}, \quad (29)$$

where, x_j is the PCE coefficient and the inner product in the numerator is given by the following multidimensional integral

$$\langle x(t, \xi(\theta)), \Psi_j \rangle = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} X(t, \xi(\theta)) \Psi_j w(\xi) d\xi. \quad (30)$$

The dimension of the integral is equal to the dimension of the vector ξ . More discussions on issues related to evaluation of integrals of the type shown in Eq. 30 are discussed in the next section.

Clearly, in the stochastic collocation technique, unlike in the Galerkin's method, one does not require transforming the original equations into any other form. Instead, the focus is on evaluating the multidimensional integrals. An inspection of Eq. 30 reveals that these integrals can be evaluated using suitable quadrature rules.

This implies selecting a set of collocation points along the domains and evaluating the structure response at these collocation points. As these methods do not alter the form of the governing equations, these methods are termed as nonintrusive methods. However, the price that one has to pay is that adopting collocation methods imply a solution of the equations of motion for various values of ξ corresponding to the collocation points. This increases the computational complexity of the problem, especially if the dimension of ξ is large. More discussions on these issues are presented in the next section.

Evaluating Multi-Dimensional Integrals

The successful implementation of PCE involves developing computationally efficient methods for the evaluation of multidimensional integrals such as Eq. 30. The multidimensional integrals are of the form

$$\langle x(t, \xi(\theta)), \Psi_j \rangle = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} X(t, \xi(\theta)) \Psi_j w(\xi) d\xi, \quad (31)$$

where, $w(\xi)$ is an appropriate weighting function. The dimension of the integral depends on the dimension of the vector ξ which again depends on the spectral content of the excitation process. Typically, in most engineering systems, the characterization of the input excitations require at least dimensions greater than 2. As in most cases closed form analytical expressions for these integrals are not possible to obtain, one has to resort to numerical methods. Therefore, one has to look for techniques to approximate these integrals with the expenditure of least possible computational effort. Various techniques for the same are available in the literature (Evans and Swartz 2000), a few of which are discussed here.

Let us consider the problem of evaluating a multidimensional integral of the form

$$\mathcal{I} = \int_{\Omega} f(\mathbf{x}) d\mathbf{x}, \quad (32)$$

where, the dimension of the integral is equal to the dimension of the vector $\mathbf{x}$ and $f(\cdot)$ is a function, which in general, can be treated to be nonlinear. It is assumed that analytical expressions for the integral in Eq. 32 are not available. Therefore, a suitable approximation for the above integral has to be developed.

Product Grid Methods

A tensor product of one-dimensional quadrature point set is used as the collocation point set in a product grid formula. Let us consider a one-dimensional quadrature rule

$$U^i(f) = \sum_{j=1}^{n_i} f(X_j^i) \cdot w_j^i \quad (33)$$

where, i denotes the dimension which in this case is $1X_j^i$ is the collocation point j in dimension i , w_j^i is the weight, and n_i is the number of collocation points in dimension i . In the multivariate case, a tensor product of such one-dimensional point set can be constructed as

$$(U^{i_1} \otimes \dots \otimes U^{i_d})f = \sum_{j_1=1}^{n_{i_1}} \dots \sum_{j_d=1}^{n_{i_d}} f(X_{j_1}^{i_1}, \dots, X_{j_d}^{i_d}) \cdot (w_{j_1}^{i_1} \otimes \dots \otimes w_{j_d}^{i_d}). \quad (34)$$

Equation 34 needs N_c collocation points. If $n_1 + \dots + n_d = n$, then $N_c = n^d$. So, for high dimensions ($d > 3$), the product grid method cannot be implemented efficiently. However, tensor product grids may be applied for problems involving lower dimensions. The collocation points and the corresponding weights can be computed using a variety of quadrature rules such as the Gauss-Legendre quadrature, Gauss-Hermite quadrature, Clenshaw-Curtis quadrature, and Gauss-Patterson quadrature.

Gauss-Legendre Quadrature

Gauss-Legendre quadrature, often simply referred to as Gauss quadrature is the most widely used method to numerically compute integrals over the domain $[-1, 1]$. The nodes are obtained

by evaluating the zeros of a Legendre polynomial of required order. If n is the order of the polynomial, then the Legendre polynomial $P_n(x)$ can be computed using the following recurrence relation:

$$\begin{aligned} (n+1)P_{n+1}(x) &= (2n+1)xP_n(x) - nP_{n-1}(x), \\ P_0(x) &= 1, P_1(x) = x. \end{aligned} \quad (35)$$

The nodes x_i obtained by computing the zeros of a n^{th} order polynomial are then used to compute the weights w_i as shown below:

$$w_i = \frac{2}{(1 - x_i^2) [P'_n(x_i)]^2}. \quad (36)$$

The nodes and weights thus computed are substituted in Eq. 33 to obtain the value of the integral. For the multidimensional case, Eq. 34 is used.

Gauss-Hermite Quadrature

When the integrand takes the form $f(x)e^{-x^2}$ and the domain of integration is $[-\infty, \infty]$, Gauss-Hermite quadrature is best suited. In this variant of Gauss quadrature, the nodes x_i are the roots of a n^{th} order Hermite polynomial and the weights are the Gaussian probability density function evaluated at these nodes. A recurrence relation for generating Hermite polynomials is given as

$$\begin{aligned} H_{n+1}(x) &= xH_n(x) - nH_{n-1}(x), \\ H_0(x) &= 1, H_1(x) = x. \end{aligned} \quad (37)$$

The above two Gauss quadrature rules are non-nested in nature. More discussions on nested quadrature rules will be discussed later.

Monte Carlo Simulations

As it was seen in the previous section, numerical evaluation of multidimensional integrals using quadrature rules is not computationally feasible for high dimensions. In such situations, Monte Carlo simulations(MCS) provide a method for

approximating the integral $\mathcal{I}$. This involves rewriting Eq. 32 as

$$\mathcal{I} = \int_{\Omega} \frac{f(\mathbf{x})}{p(\mathbf{x})} p(\mathbf{x}) \, d\mathbf{x}, \quad (38)$$

where, $p(\mathbf{x})$ can be assumed to be a probability density function (pdf), such that, $p(\mathbf{x}) \neq 0$ within the domain of integration, Ω . Equation 38 can be further rewritten as

$$\begin{aligned} \mathcal{I} &= \int_{-\infty}^{\infty} I[\mathbf{x} \in \Omega] \frac{f(\mathbf{x})}{p(\mathbf{x})} p(\mathbf{x}) \, d\mathbf{x}, \\ &= E \left[I[\mathbf{x} \in \Omega] \frac{f(\mathbf{x})}{p(\mathbf{x})} \right], \end{aligned} \quad (39)$$

where, $E[\cdot]$ is the expectation operator and $I[\cdot]$ is an indicator function that takes values of unity if $\mathbf{x}$ lies within the domain Ω and zero otherwise. Thus, an approximation for the expectation, or the mean, can be obtained as

$$\mathcal{I} = \sum_{j=1}^{N_m} I[\mathbf{x}_j \in \Omega] \frac{f(\mathbf{x}_j)}{p(\mathbf{x}_j)}, \quad (40)$$

where, N_m is the sample size. Here, $\mathbf{x}_j$ are simulated according to the pdf $p(\mathbf{x})$. The steps involved in MCS are:

1. Create a parametric model of the form $y = f(x_1, \dots, x_n)$
2. Generate samples of the parameters $x_{1_i}, \dots, x_{n_i}$, from a known probability distribution, $P(x)$
3. Evaluate the function f_i at each sample point
4. Compute the required statistical quantities like mean, variance, and higher order moments

The Monte Carlo simulation is easy to implement but suffers from a relatively lower convergence rate of $O(1/\sqrt{N_m})$.

Sparse Grid Collocation

The sparse grid method is one of the few methods to tackle the problem of the curse of dimensionality. This method was first introduced by

Smolyak and is based on constructing a multidimensional multilevel basis by truncation of the tensor product expansion of a one-dimensional basis. The number of function evaluations using a sparse grid is of $O(N(\log N)^{d-1})$ which is much lesser than that of a full tensor product which is of $O(N^d)$, where N is the number of collocation points and d is the dimension of the integral. Smolyak's algorithm finds application in a variety of high-dimensional problems like numerical integration (Gerstner and Griebel 1998; Barthelmann et al. 2000) and stochastic partial differential equations (Babuska et al. 2007; Xiu and Hesthaven 2005).

Smolyak's Algorithm

The Smolyak's quadrature rule enables creating a grid of collocation points in a multi-dimensional space with a minimal number of points. Let $f(x)$ be the function to be integrated over the d -dimensional domain Ω . Let the smooth function $f(x)$ be defined in $[0, 1]^d \rightarrow \mathfrak{R}$. For 1-dimensional case, i.e., when $d = 1$, the smooth function $f(x)$ can be approximated using the interpolation formula

$$\mathcal{U}^i(f) = \sum_{j=1}^{m_i} f(X_j^i) \cdot a_j^i, \quad (41)$$

where $\mathcal{H}^i = \{X_j^i\}$ denotes the set of nodal points defined in $[0, 1]$ and j takes values from 1 to m_i , i is an integer number and a_j^i are interpolating nodal basis functions. Note that $\mathcal{H}^i$ consists of m_i number of points.

It is next assumed that a sequence of formula corresponding to Eq. 41 can be generated for different values of i . In the multivariate case, i.e., when $d > 1$, the tensor product formula is given by

$$\begin{aligned} (\mathcal{U}^{i_1} \otimes \dots \otimes \mathcal{U}^{i_d})f &= \sum_{j_1=1}^{m_{i_1}} \dots \sum_{j_d=1}^{m_{i_d}} f(X_{j_1}^{i_1}, \dots, X_{j_d}^{i_d}) \\ &\cdot (a_{j_1}^{i_1} \otimes \dots \otimes a_{j_d}^{i_d}). \end{aligned} \quad (42)$$

This serves as the building block for the Smolyak's algorithm. A sparse interpolant $A_{q,d}$ is constructed

next using the Smolyak's algorithm using products of one-dimensional functions, given by

$$\mathcal{A}_{q,d}(f) = \sum_{q-d+1 \leq |\mathbf{i}| \leq q} (-1)^{q-|\mathbf{i}|} \cdot \binom{N-1}{q-|\mathbf{i}|} \cdot (\mathcal{U}^{i_1} \otimes \cdots \otimes \mathcal{U}^{i_d}), \quad (43)$$

where, $q \geq d$, $A_{d-1,d} = 0$, $\mathbf{i}$ denotes the multi-index $(i_1, \dots, i_d)$ and $|\mathbf{i}| = i_1 + \dots + i_d$. The index $i_k, k = 1, \dots, d$, denotes the level of interpolation along the k^{th} direction. Equation 43 implies that the interpolant is built up of one-dimensional functions of order i_k , such that the sum total $(|\mathbf{i}| = i_1 + \dots + i_k)$ across all dimensions is between $q - d + 1$ and q . Equation 43 can be rewritten in terms of incremental interpolants, Δ^i , given by

$$\Delta^i = \mathcal{U}^i - \mathcal{U}^{i-1} \quad (44)$$

with $\mathcal{U}^0 = 0$. Then, Smolyak's formula for computing a d -dimensional integral is

$$\mathcal{A}_{q,d}f = \sum_{i=1}^{q-1} (\Delta_i \otimes A_{q-1,d-1})f. \quad (45)$$

The interpolation, $\mathcal{A}_{q,d}f$, can be approximated by evaluating the function at specific nodes given by the sparse grid. A sparse grid $\mathcal{H}_{q,d}^i$ can be constructed using the points of the multivariate Smolyak's formula. If $\mathbf{X}^i$ is the set of points $\{X_1^i, \dots, X_{m_i}^i\}$ corresponding to $\mathcal{U}$, then

$$\mathcal{H}_{q,d} = \bigcup_{|\mathbf{i}| \leq q+d-1} \mathbf{X}_{i_1} \times \cdots \times \mathbf{X}_{i_d}, \quad (46)$$

where, $|\mathbf{i}| = i_1 + \dots + i_d$.

The construction of the interpolant using Smolyak's algorithm enables improving the level of approximation which uses all the previously generated interpolant functions. Thus, to extend the interpolation from level $i - 1$ to i , the function needs to be additionally evaluated at only the set of grid points $X_{\Delta}^i = X^i \setminus X^{i-1}$, where the bar indicates set difference. The set of grid

points at which the function needs to be evaluated for improving the interpolation from $(q - 1)$ order to q order is given by

$$\Delta \mathcal{H}_{q,d} = \bigcup_{|\mathbf{i}|=q} (X_{\Delta}^{i_1} \otimes \cdots \otimes X_{\Delta}^{i_d}), \quad (47)$$

where $i_1, \dots, i_d$ have the same meaning as before. The steps involved in generating a sparse grid and then utilizing it for computing a multidimensional integral are given below:

1. Choose a suitable one-dimensional quadrature with nodes X_i and weights a_i
2. Based on the number of dimensions d of the problem, decide the level of sparse grid q
3. Construct a sparse grid, $\mathcal{H}_{q,d}^i$, by evaluating Eq. 46
4. Define the difference quadrature formula $\Delta^i f$ as given in Eq. 44. Here f is the function which is to be integrated
5. Using Eq. 45, evaluate the integral of the function $f(\mathbf{x})$ over the domain Ω

The size of the sparse grid depends on the following factors:

- The level, q , of approximation adopted for the function
- The dimension of integration d
- The type of one-dimensional quadrature formula being used

Typically, the quadrature formulae that can be used are either of the non-nested type such as the Gauss-Legendre and Gauss-Hermite quadrature rules or nested type. A brief discussion on a couple of nested quadrature rules are presented next.

Nested Univariate Quadrature Rules

Some of the quadrature schemes have sets of nodal points which are nested. This means the set of nodal points at $(i + 1)^{th}$ level, X_{i+1} , includes all points in the set X_i . Symbolically this is written as $X_i \subset X_{i+1}$. Therefore, while moving to a higher level, only the points in the difference set, $X_{i+1} - X_i$, need to be considered for function

evaluation, thus saving a huge amount of computational effort (Barthelmann et al. 2000). The use of such nested quadrature schemes result in grids which are sparse and require fewer collocation points while evaluating multidimensional integrals. Specific forms of such quadrature schemes are discussed next.

Clenshaw-Curtis Quadrature

The Clenshaw-Curtis quadrature rule is widely used for generating sparse grids. It uses the roots of Chebyshev polynomials as the nodes. For any choice of $m_i > 1$, the nodes are given by

$$x_j^i = -\cos \frac{\pi \cdot (j-1)}{m_i-1}, \quad j = 1, \dots, m_i. \quad (48)$$

Also, when $m_i = 1$, $x_1^i = 0$. A nested set of points can be obtained by setting the following relation for m_i

$$m_i = 2^{i-1} + 1, \quad i > 1. \quad (49)$$

m_1 must be set to 1 to have the fewest number of points for a large d . Since m_1 is odd for any $i > 1$, the corresponding weights are given by

$$w_j^i = w_{m_i+1-j}^i = \frac{2}{m_i-1} \left(1 - \frac{\cos(\pi \cdot (j-1))}{m_i \cdot (m_i-2)} - 2 \sum_{k=1}^{\frac{(m_i-3)}{2}} \frac{1}{4k^2-1} \cdot \cos \frac{2\pi k \cdot (j-1)}{m_i-1} \right), \quad (50)$$

for $j = 2, \dots, m_i - 1$. The two missing weights are given by

$$w_1^i = w_{m_i}^i = \frac{1}{m_i \cdot (m_i-2)}, \quad (51)$$

where, m_i are given by Eq. 49.

Gauss-Patterson Quadrature

The Gauss-Patterson quadrature technique is an extension of the Gauss quadrature. In a regular Gauss quadrature, the set of nodes for a $(n+1)$ point quadrature is completely independent of the set of nodes for n point quadrature. This means that with an increase in n , the function evaluations already performed for a lower n value cannot be reused. Kronrod (Gerstner and Griebel 1998) proposed an optimal method by which all the nodes of lower order can be reused. This is carried out by augmenting a new set of nodes to the old set of nodes while moving from a lower level quadrature to one of a higher level. These new nodes are generally obtained as the roots of Stieltjes polynomials. Patterson (Gerstner and Griebel 1998) extended Kronrod's construction by developing an iterated scheme to find a nested set of nodes.

Product Grids

To illustrate the effect that the type of quadrature rule has on the sparse grid size, a series of two dimensional grids have been shown in Figs. 2, 3, 4, and 5. They are compared with the full tensor product grid. As can be observed, a considerable reduction in the number of nodal points between the full tensor grid and the sparse grid is seen in all the cases. For example, for a Clenshaw-Curtis grid with $d=2$ and $q=3$, the sparse grid requires 13 function evaluations while the full grid requires 25 function evaluations. The reduction in computations is therefore about 48 %. In the following section, the accuracy of this algorithm is examined with respect to a test function.

Accuracy of Sparse Grid Collocation

In this section, the accuracy of the sparse grid collocation technique for computing numerically multidimensional integrals is examined. A test function is examined whose exact numerical integral is available. For the one-dimensional quadrature rules used in the Smolyak's algorithm, only the nested quadrature rules, namely, the Clenshaw-Curtis(CC) rule and the Gauss-Patterson(GP) rule, have been used.

The numerical evaluation of the following integral is considered

$$\mathcal{I} = \int_{[0,1]^d} (1 + 1/d)^d \prod_{i=1}^d (x_i)^{(1/d)} \mathrm{d}\mathbf{x}, \quad (52)$$

where d denoted the dimension of the integral. Note that x is a d -dimensional vector. The exact value of the integral for any value of d is unity. A numerical estimate of the above integral is computed using both CC and GP quadrature rules. For a given dimension d , several levels of approximation q were considered and a comparison of the accuracy of the estimates are examined. The dimension d is varied from 2 to 6. Table 1 gives details of the number of function calls and the error incurred using the two methods. It is observed that for a given d , as level q is increased, the error in the approximation reduces. The error when GP quadrature rule is used is less than when CC is used.

However, as the level increases, the number of collocation points required in GP is usually more than twice than that when CC quadrature rule is used. For higher dimensions, GP appears to be more accurate than CC. For example, when $d = 6$, using GP with level 3 requires 97 function calls with accuracy of $O(10^{-3})$ while the same accuracy is obtained using CC with level 7 which requires 15121 function evaluations. Clearly, using GP with lower levels of approximation is better than using CC with higher levels of approximation. Thus, sparse grids based on GP rule will be used in all further studies carried out here.

Numerical Examples

The developed algorithm is used to obtain the response of a few randomly excited dynamical systems. A Duffing oscillator is considered whose

response has been obtained through the stochastic collocation and the sparse grid collocation methods. The Galerkin's method is avoided due to difficulties mentioned in section [Stochastic Galerkin Method](#). Next, a two-dimensional airfoil subjected to unsteady gusty wind flow regime is considered. The response is obtained through the sparse grid collocation method. Once the response of the vibrating systems is obtained in terms of a polynomial chaos expansion, approximations for the joint pdf of the response and its instantaneous time derivative are obtained using simulations. Subsequently, the crossing statistics are calculated using Rice's formula. Finally, estimates of the first passage failure probability and expected fatigue damage are calculated using the method discussed in sections [First Passage Failures](#) and [Random Fatigue Damage](#).

Duffing Oscillator

The problem of estimating the response of a randomly excited Duffing oscillator is considered. The governing equation of motion of a Duffing oscillator is given by

$$m\ddot{X} + c\dot{X} + kX + k_1X^3 = f(t, \theta), \quad (53)$$

where, m is the mass, c is damping, k is the linear stiffness, and k_1 is the nonlinear stiffness. When k_1 is small, the effect of the nonlinearity is not significant. Thus, in the numerical example, k_1 is assumed to be (a) 2 times k and (b) 10 times k . The numerical values considered are $m = 5$ kg, $c = 1.414$ Ns/m, $k = 1,000$ N/m, and $k_1 = 2 \times 10^3$ N/m³ and 1×10^4 N/m³.

Full Grid Stochastic Collocation

The excitation, $f(t, \theta)$, assumed to be a stationary Gaussian process, is approximated as a K-L expansion truncated up to M terms as shown below:

$$f(t, \theta) = f_0 + \sum_{i=1}^M \xi_i(\theta) \sqrt{\lambda_i} \phi_i(t). \quad (54)$$

Here, θ represents the stochastic dimension. The autocorrelation function of the excitation is given by

$$R_{ff}(\tau) = \sigma_f^2 e^{-c_0 \tau^2}, \quad (55)$$

where, $\sigma_f = 1$ and $c_0 = 1 \times 10^{-3}$. Table 2 lists the 10 highest eigenvalues of the spectral representation. First, the coefficients of the PCE representation are obtained using the method of stochastic collocation using a full tensor grid. As the number of collocation points becomes very large when a full tensor grid is used, the number of terms included in the K-L representation is limited to 2. A fifth order Gauss-Hermite quadrature is used. This results in 25 collocation points implying 25 deterministic runs of the governing equations of motion to estimate the PCE coefficients. A 3-term PCE representation is obtained for the response when $k_1 = 2 \times 10^3$ N/m³. These results are compared with those obtained from full-scale Monte Carlo simulations with 1×10^4 samples. Figures 6 and 7 respectively compare the pdf of the displacement and the velocity. While the pdf of the displacement appears to have a very close resemblance, a slight discrepancy is observed in the pdf of the velocity.

However, as the nonlinearity is increased, a 3-term PCE representation is found to be inadequate. When k_1 is increased to 1×10^4 N/m³, a 5-term PCE representation of the response is required. Comparisons between the mean of the displacement and the velocity are shown in Figs. 8 and 9, while the corresponding variance plots are shown in Figs. 10 and 11. It can be observed that while the mean have a good

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,

Fig. 6 Marginal pdf $p_x(x)$; $k_1 = 2 \times 10^3 \text{ N/m}^3$

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,

Fig. 7 Marginal pdf $p_{\dot{x}}(\dot{x})$; $k_1 = 2 \times 10^3 \text{ M/m}^3$

match, the variance plots reveal a slight mismatch. This implies that probably a 5-term PCE representation is not adequate and that higher order PCE representations are necessary. This becomes clear when one compares the marginal pdfs of the displacement and velocity of the Duffing oscillator shown in Figs. 11, 12, and 13. A significant mismatch is observed between the pdfs obtained from the 5-term PCE representation and Monte Carlo simulations. However, the CPU time required in the proposed method, which depends on the number of solutions of the governing equations is significantly smaller.

For a 5-term PCE representation, this required 25 solutions of the governing equation. In comparison, governing equation was solved 1×10^4 times when Monte Carlo simulations were used.

Sparse Grid Stochastic Collocation

Next, the sparse grid collocation method discussed in section [Sparse Grid Collocation](#) is used to obtain the PCE representation of the response. The use of sparse grid algorithm enables considering higher number of terms in the K-L representation of the excitation. Thus, now a 5-term K-L expansion is considered.

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach, Fig. 8 Mean displacement; $k_1 = 1 \times 10^4 \text{ N/m}^3$

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach, Fig. 9 Mean velocity; $k_1 = 1 \times 10^4 \text{ N/m}^3$

The sparse grid collocation method is now used to obtain the PCE coefficients of the response. A Gauss-Patterson based sparse grid collocation of level 6 is used for estimating the PCE coefficients. This involves a total 5,503 collocation points implying the need to solve an equivalent number of deterministic runs of the governing equation. This is still half the number of times the governing equation that needs to be solved using Monte Carlo simulations. The marginal pdfs of the displacement and velocity are shown in Figs. 14 and 15 respectively. A fairly good resemblance is observed. Figure 16 compares

the contour plots of the joint pdf $p_{X\dot{X}}(x, \dot{x})$ obtained using the proposed method and MCS. The mean crossing statistics are then computed using these joint pdf by numerically integrating Rice's formula. The mean crossing intensities calculated for various levels using the approximated joint pdf $p_{X\dot{X}}(x, \dot{x})$ obtained using the PCE-based method and MCS are shown in Fig. 17. Though the trends are observed to be very similar, the desired match is not obtained at the mean region. The first passage failure probabilities for various threshold levels are next calculated and are shown in Fig. 18. A very good

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,

Fig. 10 Variance of displacement; $k_1 = 1 \times 10^4$

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,

Fig. 11 Variance of velocity; $k_1 = 1 \times 10^4 \text{ N/m}^3$

match, when plotted in the log scales, is observed. This indicates that the order of error is negligible in comparison to the failure probability levels being estimated.

Next, estimates of the expected fatigue damage are obtained using the spectral method discussed in section [Random Fatigue Damage](#). These predictions are compared with those obtained from MCS using the procedure outlined in the previous section. For the sake of illustration, the numerical values for K and β are taken arbitrarily. The expected fatigue damage is

calculated for various values of β ranging from 2 to 8. These are shown in Fig. 19. It is observed that a very good match is observed with the proposed method and Monte Carlo simulations.

It is seen from the above results that the stochastic collocation method and the sparse grid method perform well in obtaining the response of randomly excited vibrating system. The sparse grid approach is next applied to a highly nonlinear fluid–structure interaction problem for response analysis and subsequently, reliability estimation.

2-D Airfoil Subjected to Unsteady Gusty Wind Flow Regime

Next, the oscillations of a two-dimensional airfoil in unsteady random flow are considered. The airfoil system is a nonlinear aeroelastic system with two degrees of freedom in the pitch and heave directions. The schematic diagram of the two-dimensional airfoil is shown in Fig. 20.

The governing equations of motion for the airfoil can be expressed as (Fung 1955)

$$\epsilon'' + x_\alpha \alpha'' + 2\zeta_\epsilon \frac{\bar{\omega}}{U} \epsilon' + \left(\frac{\bar{\omega}}{U}\right)^2 (\epsilon + \beta_\epsilon \epsilon^3) = -\frac{1}{\pi\mu} C_L(\tau), \quad (56)$$

$$\frac{x_\alpha}{r_\alpha^2} \epsilon'' + \alpha'' + 2\frac{\zeta}{U} \alpha' + \frac{1}{U^2} (\alpha + \beta_\alpha \alpha^3) = \frac{2}{\pi\mu r_\alpha^2} C_M(\tau). \quad (57)$$

Here, $\epsilon = h/b$ is the nondimensional heave displacement, α is the pitch angle, m is the total mass per unit span, r_α is the radius of gyration about the elastic axis, ζ_ϵ and ζ_α are the damping ratios in plunge and pitch respectively, β_ϵ is the heaving stiffness co-efficient, β_α is the pitching stiffness, $a_h b$ denotes the distance of the elastic axis from the mid chord, and $x_\alpha b$ is the distance of the center of mass from the elastic axis; see Fig. 20

R

for a schematic. U is the nondimensional stream velocity given by $U = v/(b\omega_\alpha)$, $\overline{\omega} = (\omega_\epsilon/\omega_\alpha)$, where, ω_ϵ and ω_α are respectively the natural frequencies of the uncoupled plunging and pitching modes and $\tau = vt/b$ is the nondimensional time. The nonhomogeneous terms $C_L(\tau)$ and $C_M(\tau)$ represent the forcing terms and are usually represented as a set of coupled second order differential equations which are functions of α and ϵ (Alighanbari and Price 1996). Thus, these equations constitute a problem in fluid–structure interactions. The exponent $(\cdot)'$ represents differentiation with

respect to nondimensional time. Here, the coefficients and β_ϵ and β_α could be nonlinear functions of ϵ and α . If the flow is assumed to be incompressible and inviscid, the lift and pitching moment coefficients $C_L(\tau)$ and $C_M(\tau)$ are as given by Fung (1955) and are expressed as

$$\begin{aligned}
 C_L(\tau) = & \pi(\epsilon'' - a_h \alpha'' + \alpha') \\
 & + 2\pi \left\{ \alpha(0) + \epsilon'(0) + \left[\frac{1}{2} - a_h \right] \alpha'(0) \right\} \phi(\tau) \\
 & + 2\pi \int_0^\tau \phi(\tau - \sigma) \left[\alpha'(\sigma) \epsilon''(\sigma) + \left[\frac{1}{2} - a_h \right] \alpha''(\sigma) \right] d\sigma,
 \end{aligned} \tag{58}$$

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,

Fig. 16 Contour plot of $p_{xx}(x, \dot{x})$

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach, Fig. 17 Mean upcrossing intensity; Duffing oscillator

$$\begin{aligned}
 C_M(\tau) = & \pi \left[\frac{1}{2} + a_h \right] \times \left\{ \alpha(0) + \epsilon'(0) + \left[\frac{1}{2} - a_h \right] \alpha'(0) \right\} \phi(\tau) \\
 & + \pi \left[\frac{1}{2} + a_h \right] \times \int_0^T \phi(\tau - \sigma) \left\{ \alpha'(\sigma) + \epsilon''(\sigma) \right. \\
 & \left. + \left[\frac{1}{2} - a_h \right] \alpha''(\sigma) \right\} d\sigma \\
 & + \frac{\pi}{2} a_h (\epsilon'' - a_h \alpha'') - \left[\frac{1}{2} - a_h \right] \frac{\pi}{2} \alpha' - \frac{\pi}{16} \alpha''.
 \end{aligned}
 \quad (59)$$

Here $\epsilon(0)$, $\epsilon'(0)$, $\alpha(0)$ and $\alpha'(0)$ respectively denote the initial conditions, $\phi(\tau)$ is the Wagner function expressed as

$$\phi(\tau) = 1 - \psi_1 e^{-\epsilon_1 \tau} - \psi_2 e^{-\epsilon_2 \tau} \quad (60)$$

and the constants $\psi_1 = 0.165$, $\psi_2 = 0.355$, $\epsilon_1 = 0.0455$, and $\epsilon_2 = 0.3$ are as reported in Lee et al. (1998).

Fig. 19 Expected fatigue damage; Duffing oscillator

R

In the absence of any gusts, the flow is constant with mean velocity U . The deterministic bifurcation plot for α is shown in Fig. 21. It is seen that bifurcation occurs at $U = 6.285$, after which the systems starts exhibiting limit cycle oscillations (LCO) (Alighanbari and Price 1996). The two branches after $U = 6.285$ represent the minimum and maximum of the LCO amplitude. The phase plot at $U = 16$ as shown in Fig. 22 depicts these limit cycle oscillations.

However, in real life situations, wind flow is not deterministic but has random fluctuations about a mean value. Hence, this randomness must be included in the model in order to gain better insights on the behavior of system. Therefore, the nondimensional free stream velocity U is assumed to be a stationary Gaussian random process with the autocorrelation function as given in Eq. 55 with $\sigma_f = 1$ and $c_0 = 1 \times 10^{-6}$. This implies a correlation length of 2.628×10^3 s. It must be

noted that wind velocity has very low frequency content with very large correlation lengths. The wind flow is represented by a KL expansion of the form

$$U = U_0 + \sum_{i=0}^N \xi_i(\theta) \sqrt{\lambda_i} \phi_i(t). \quad (61)$$

For a nondimensional time duration of 3,600 and $c_0 = 1e^{-6}$, it can be seen from Table 3 that only the first five eigenvalues λ are significant. Hence, a reasonable approximation for U is obtained with a five term K-L expansion. The mean nondimensional speed U_0 is taken as 16. The numerical values of the remaining parameters are taken to be the same as that in Lee

et al. (1998): $\mu = 100$, $\overline{\omega} = 0.2$, $a_h = -0.5$, $x_\alpha = 0.25$, $\zeta_\alpha = 0$, $\zeta_\epsilon = 0$, $r_\alpha = 0.5$.

It can be seen that the governing equations of motion, given by Eqs. 56–59 constitute a set of coupled second order integrodifferential equation and are hence highly nonlinear. These equations can be recast as a set of eight coupled first order nonlinear differential equations by introducing four auxiliary state variables; see Alighanbari and Price (1996). The system is solved using an adaptive 4th order Runge–Kutta algorithm and the results are presented in Figs. 23, 24, and 25.

Twelve thousand realizations of the response are generated using both PCE and full-scale Monte-Carlo simulation. A Gauss-Patterson sparse grid of level 6 is used to obtain the PCE coefficients. The number of function evaluations in PCE and MCS are 5,503 and 12,000 respectively. The marginal pdfs of the pitching displacement and pitching velocity are shown in Figs. 23 and 24 respectively. A fairly good resemblance is observed between the predictions obtained by the proposed method and those obtained from MCS.

A PCE representation of the response enables generating samples of time histories of the response. Thus, next the joint pdf $p_{\alpha\dot{\alpha}}(\alpha, \dot{\alpha})$ are constructed and its contour plots are shown in Fig. 25. The corresponding pdf obtained from MCS are also plotted in the same figure for comparison. A very good agreement between the two is observed.

The first passage failure probabilities are next computed for various threshold levels. These are shown in Fig. 26. A good agreement between the predictions of the proposed method and MCS are observed. The expected fatigue damage obtained using the two methods for various values of f_t are shown in Fig. 27. It is seen that the proposed method leads to fairly close resemblance with MCS predictions. However, as f_t becomes larger, the proposed method slightly overestimates the expected fatigue damage and hence is more conservative from the perspective of reliability and residual life assessment.

Summary

The focus of this entry has been on demonstrating the use of spectral-based methods for time-variant reliability estimation in nonlinear structural systems subjected to random loadings. The crux of this approach lies in approximating the joint pdf of the response and its instantaneous time derivative and subsequently using the Rice’s integral to numerically evaluate the crossing statistics. The loadings have been assumed to be stationary, Gaussian random processes and are represented in terms of the Karhunen-Lo  ve series expansion. Subsequently, polynomial chaos expansions have been used to represent the structure response. In using PCE, the main difficulty lies in estimating the PCE coefficients. In the literature, two general approaches for estimating the PCE coefficients have been discussed. The stochastic Galerkin method is an intrusive approach as the application of this method significantly alters the form of the governing equations of motion. Importantly, the use of this approach requires *a priori* evaluation of the multidimensional expectations.

The alternative and preferred numerical approach is to use the concept of stochastic collocation, which is a nonintrusive approach. This

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,
Fig. 23 Marginal pdf $p_x(\alpha)$

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,
Fig. 24 Marginal pdf $p_{\dot{x}}(\dot{\alpha})$

entry has focused on the use of the sparse grid collocation method based on Smolyak's algorithm as a computationally efficient tool for approximating the joint probability density function of the response and its instantaneous time derivative. For highly nonlinear problems such as the fluid-structure interaction problem considered in section 2-D Airfoil Subjected to Unsteady Gusty Wind Flow Regime, the proposed method provides an alternative method for obtaining the crossing statistics of the response. Usually, problems of this genre can be solved using Monte

Carlo simulations only. Though the proposed method requires significant computational effort, this is still less than 50 % of the computational efforts in comparison to Monte Carlo simulations.

The spectral-based method discussed in this entry is computationally efficient as long as the number of collocation points is less than the sample size used in Monte Carlo simulations. This in turn, depends on the number of terms retained in the PCE representation of the response. As the bases for the PCE representation of the response

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,

Fig. 25 Contour plot of $p_{\alpha\dot{\alpha}}(\alpha, \dot{\alpha})$

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,

Fig. 26 Probability of failure 2-D airfoil

in turn depends on the basis dimension of the input loadings, this method is not suitable for problems where the excitations have a large spectral bandwidth. This is because the number of nonzero eigenvalues for the spectral content of the loading would be large. This, in turn, implies that the stochastic dimension would be large making the method computationally too intensive even with the application of the sparse grid-based algorithms. In such situations, MCS is more computationally efficient.

The excitations considered in this study have been limited to Gaussian excitations. This however

is not a restricting feature. For non-Gaussian excitations, an appropriate PCE representation can be obtained for the input as long as a transformation is available from an equivalent Gaussian process. This aspect of the study has not been addressed in this study.

The present study has considered only the randomness in the excitations, with the structure properties being considered to be deterministic. The studies can be extended to include uncertainties in the material properties as well. This however would increase the computational costs associated with the problem. An alternative

Reliability Analysis of Nonlinear Vibrating Systems-Spectral Approach,
Fig. 27 Expected fatigue damage; 2-D airfoil

approach could be to represent the system uncertainties in the spectral domain only and use hybrid approaches that make use of the spectral method discussed in this work along with Monte Carlo simulations. The proposed method can be used efficiently for spectral stochastic finite element method in problems involving characterization of uncertainties across multiple scales. Studies along these lines are currently being pursued in the group.

Introduction

Reliability is a fundamental attribute required to any structure, equipment, and system, because of the impact of failures on production efficiency, safety, and asset integrity. Its technical description requires two successive phases, one of analysis and one of estimation, which are at the basis of what is today called reliability engineering.

The first phase in the analysis of the reliability of a structure, equipment, or system is aimed at identifying the hazards associated to its operation and the mechanisms of failure to which it can be exposed during operation. The analysis is typically qualitative, based on expert judgment but driven by a systematic framework of procedures for organizing the expert knowledge. The output of the analysis is a list of the hazards and failure mechanisms, with technical information on the consequences they can provoke to the function provided by the structure, equipment, or system,

and indications on how to protect from them or mitigate them by design or maintenance. Completeness of this phase of the analysis is obviously fundamental, for the successive quantitative estimation.

The second and final phase aims at the estimation of the probability of failure of the structure, equipment, or system. A fundamental issue in this phase is the uncertainty in the failure occurrences, which must be given due account in the quantitative modeling.

In this entry, concepts and methods of reliability analysis and estimation are introduced and explained. Some of the material is adapted from Zio (2009a, b).

History of Reliability Engineering

The needs for reliability have significantly emerged in relation to mass production for the manufacturing of large quantities of goods from standardized parts (rifle production at the Springfield Armory, 1863, and Ford Model T car production, 1913) (Saleh and Marais 2006). A catalyst for this was the vacuum tube, specifically the triode invented by Lee de Forest in 1906, which at the onset of WWII initiated the electronic revolution, enabling a series of applications such as the radio, television, radar, and others. The vacuum tube is by many recognized as the active element that allowed the Allies to win the so-called wizard war. At the same time, it was also the main cause of equipment failure: tube replacements were required five times as often as all other equipment. After the war, this experience with the vacuum tubes prompted the US Department of Defense (DoD) to initiate a number of studies for looking into these failures.

A similar situation was experienced on the other side of the warfront by the Germans, where Chief Engineer Lusser, a program manager working in Peenemunde on the V1, prompted the systematic analysis of the relations between system failures and components faults.

These and other military-driven efforts eventually led to the rise of the new discipline of

reliability engineering in the 1950s, consolidated and synthesized for the first time in the Advisory Group on Reliability of Electronic Equipment (AGREE) report in 1957. The AGREE was jointly established in 1952 between the DoD and the American Electronics Industry, with the mission of (Coppola 1984):

1. Recommending measures that would result in more reliable equipment
2. Helping to implement reliability programs in government and civilian agencies
3. Disseminating a better education on reliability

Several projects, still military funded, developed in the 1950s from this first initiative (Coppola 1984; Knight 1991; Denson 1998). Failure data collection and root cause analyses were launched with the aim of achieving higher reliability in components and devices. These led to the specification of quantitative reliability requirements, marking the beginning of the contractual aspects of reliability. This inevitably brought the problem of being able to estimate and predict the reliability of a component before it is built and tested: this in turn led in 1956 to the publication of a major report on reliability prediction techniques entitled “Reliability Stress Analysis for Electronic Equipment” (TR-1100) by the Radio Corporation of America (RCA), a major manufacturer of vacuum tubes. The report presented a number of analytical models for estimating failure rates and can be considered the direct predecessor of the influential military standard MH-217 first published in 1961 and still used today to make equipment reliability predictions.

In the 1960s, the discipline of reliability engineering proceeded in two directions:

- Increased specialization in the discipline by sophistication of the techniques, e.g., redundancy modeling, Bayesian statistics, Markov chains, etc., and by the development of the concepts of reliability physics to identify and model the physical causes of failure and of structural reliability to analyze the integrity of buildings, bridges, and other constructions

- Shift of the attention from component reliability to system reliability and availability, to cope with the increased complexity of the engineered systems, like those developed as part of military and space programs like the Mercury, Gemini, and Apollo ones

Three broad areas characterized the development of reliability engineering in the 1970s:

- The potential of system-level reliability analysis (Barlow and Proschan 1975) motivated the rational analysis of the safety of complex systems such as the nuclear power plants (WASH-1400 1975).
- The increased reliance on software in many systems led to the growth of focus on software reliability, testing, and improvement (Moranda 1981).
- The lack of interest on reliability programs that managers often showed already at that time sparked the development of incentives to reward improvement in reliability on top of the usual production-based incentives.

In the following years, the last 40 years, the scientific and technical community has witnessed an impressive increase of developments and applications of reliability engineering, aimed at rationally coping with the challenges brought by the growing complexity of the systems and practically taking advantage of the computational power becoming available at reasonable costs. These developments and applications have been driven by a shift from the traditional industrial economy, valuing products, to the modern economy centered on service. This has led to an increased attention to service availability as a most important quality and to a consequent push in the development of techniques for its quantification, which requires considering a number of interrelated processes of component degradation, of failure and repair, and of diagnostics, prognostics, and maintenance.

Nowadays, reliability engineering is a well-established, scientific discipline which aims at providing an ensemble of formal methods to

investigate the uncertain boundaries between system operation and failure, by addressing the following questions (Cai 1996; Aven and Jensen 1999):

- Why failures occur, e.g., by using the concepts of reliability physics to discover causes and mechanisms of failure and to identify consequences
- How to develop reliable structures, equipment, and systems, e.g., by reliability-based design
- How to measure and test reliability in design, operation, and management
- How to maintain systems reliable, by fault diagnosis, prognosis, and maintenance

Reliability engineering addresses these questions by structured and formal methods of analysis, which entail the representation and modeling of the structure, equipment, or system based on the available knowledge and information, the quantification of the model based on the available data, and the representation, propagation, and quantification of the uncertainty in the behavior of the structure, equipment, or system as inferred from the knowledge, information, and data available, which is always incomplete, imprecise, and often scarce.

Methods of Reliability Analysis: Failure Mode and Effects Analysis (FMEA)

In this section, the qualitative analysis aimed at identifying the hazards and failure mechanisms associated to the operation of a system is exemplified by way of a very common method known as failure mode and effects analysis (FMEA). Actually in practice, a FMECA (failure mode, effects, and criticality analysis) is typically performed to arrive at also assigning a criticality class to each failure mode, for example, according to the following ranking:

- *Safe* = no relevant effects.
- *Marginal* = partially degraded system but no damage to humans.

- *Critical* = system damaged and damages also to humans; if no protective actions are undertaken, the accident could lead to loss of the system and serious consequences on the humans.
- *Catastrophic* = loss of the system and serious consequences on humans.

Such analysis is inductive, based on expert knowledge for identifying the failure modes and inducing their effects and eventually assigning their combined criticality. The analysis aims at identifying, in particular, those failure modes which could impair the function intended for the system, possibly leading to disabled operation or, even, initiating accidents with safety consequences.

The analysis is driven by a systematic procedure, whose basic tasks can be simplified as follows:

1. Decompose the system in functionally independent subsystems; for each subsystem identify the various operation modes (e.g., start-up, regime, shutdown, maintenance, etc.) and its configurations when operating in such modes (e.g., valves open or closed, pumps on or off, etc.).
2. For each subsystem in each of its operation modes, compile a table such as Table 1 below, listing all subsystem components, their failure modes, and their effects on the functionality of other neighboring components, on the subsystem, and eventually the whole system (Henley and Kumamoto 1992).

The analysis considers primarily the effects of single failures, except for the case of standby components for which the effects are considered conditioned on the failure of the main component.

For complex systems, a FMECA can be rather burdensome, in spite of the fact that several computer tools have been developed and made available on the market to aid organizing the implementation. Often, this analysis is used in support to reliability-centered maintenance programs.

Reliability Estimation and Analysis, Table 1 Typical FME(C)A table (Henley and Kumamoto 1992)

System											
Operation mode											
Component	Description	Failure mode	Effects on other components	Effects on subsystem	Effects on plant	Probability	Criticality	Detection methods	Protections and mitigation	Remarks	
		Failure modes relevant for the operational mode indicated	Effects of failure mode on adjacent components and surrounding environment	Effects on the functionality of the subsystem	Effects on the functionality and availability of the entire plant	Probability of failure occurrence (sometimes qualitative)	Criticality rank of the failure mode on the basis of its effects and probability (qualitative estimation of risk)	Methods of detection of the occurrence of the failure event	Protections and measures to avoid the failure occurrence	Remarks and suggestions on the need to consider the failure mode as accident initiator	

Methods of Reliability Estimation

In reliability engineering, the quantitative phase is focused on the time to failure T , which is a continuous random variable whose cumulative distribution function (cdf) $F_T(t)$ and probability density function (pdf) $f_T(t)$ are typically called the failure probability and density functions at time t . The complementary cumulative distribution function (ccdf) $R(t) = 1 - F_T(t) = P(T > t)$ is called *reliability* at time t and gives the probability that the structure, equipment, or system survives up to time t with no failures.

Another description of the failure behavior in time of a structure, equipment, or system, commonly used by reliability engineers and practitioners, is given by the probability that it fails within a time interval dt (mathematically infinitesimal) knowing that it has never failed before the lower bound, t , of the interval. This probability is expressed in terms of the product of the interval dt times a conditional probability density called *hazard function* or *failure rate* and usually indicated by the symbol $h_T(t)$:

$$\begin{aligned} h_T(t)dt &= P(t < T \leq t + dt | T > t) \\ &= \frac{P(t < T \leq t + dt)}{P(T > t)} = \frac{f_T(t)dt}{R(t)} \end{aligned} \quad (1)$$

The hazard function $h_T(t)$ gives the same information of the pdf and cdf to whom it is univocally related by Eq. 1 and its integration, i.e.,

$$F_T(t) = 1 - e^{-\int_0^t h_T(s)ds} \quad (2)$$

Figure 1 shows some common patterns of $h_T(t)$ in time, encountered in practice (Zeng 1997).

In the most general case, the hazard function follows the so-called “bathtub” curve (Fig. 1, case 1), which shows three distinct phases in the life of a component: the first phase corresponds to a failure rate decreasing with time, and it is characteristic of the *infant mortality* or *burn-in* period whereupon the more the structure, equipment, or system lives with no failures, the lower its probability of failure itself becomes (this period is

important for warranty analysis); the second phase, called *useful life*, corresponds to a failure rate independent of time: during this period, failures occur at random times with no influence on the usage time of the structure, equipment, or system; finally, the last phase sees an increase in the failure rate with time and corresponds to the development of aging processes.

Deviations from this general behavior (Fig. 1, cases 2–5) occur depending on the burn-in and maintenance procedures adopted by the particular industry.

The Weibull distribution is often used in reliability practice to describe the failure behavior in time of a structure, equipment, or system. The cdf of the failure time random variable is

$$F_T(t) = P(T \leq t) = 1 - e^{-\lambda t^\alpha} \quad (3)$$

and the corresponding pdf is

$$\begin{aligned} f_T(t) &= \lambda \alpha t^{\alpha-1} e^{-\lambda t^\alpha} & t \geq 0 \\ &= \lambda \alpha t^{\alpha-1} e^{-\lambda t^\alpha} & t < 0 \end{aligned} \quad (4)$$

The expected value and variance of the Weibull distribution are

$$\begin{aligned} E[T] &= \frac{1}{\lambda} \Gamma\left(\frac{1}{\alpha} + 1\right) \\ \text{Var}[T] &= \frac{1}{\lambda^2} \left(\Gamma\left(\frac{2}{\alpha} + 1\right) - \Gamma\left(\frac{1}{\alpha} + 1\right)^2 \right) \end{aligned} \quad (5)$$

where the Gamma function $\Gamma(\cdot)$ is the generalization to non-integer numbers of the factorial and is defined as

$$\Gamma(k) = \int_0^\infty x^{k-1} e^{-x} dx \quad k > 0 \quad (6)$$

which by integration by parts yields

$$\Gamma(k) = (k-1)\Gamma(k-1) \quad (7)$$

For $\alpha < 1$, the distribution can represent the burn-in period; for $\alpha > 1$, it can describe the aging period; for $\alpha = 1$, the distribution is called exponential, characterized by a constant failure rate,

Reliability Estimation and Analysis, Fig. 1 Patterns of time evolution of the hazard function (or failure rate) (Zeng 1997)

and describes the useful part of the life of the structure, equipment, or system. In this latter case, the expected value of the distribution is

$$E[T] = \frac{1}{\lambda} \quad (8)$$

and is called *mean time to failure* (MTTF).

The reliability of a series system made of N components, whose logic of operation is that all components must function for the system to function, is

$$R(t) = \prod_{i=1}^N R_i(t) \quad (9)$$

$R_i(t)$, $i = 1, 2, \dots, N$ are the individual components' reliabilities.

For exponential components of individual reliabilities $R_i(t) = e^{-\lambda_i t}$, $i = 1, 2, \dots, N$, the system reliability becomes $R(t) = e^{-\lambda t}$, where

$$\lambda = \sum_{i=1}^N \lambda_i = \text{system failure rate} \quad (10)$$

$$m = \frac{1}{\lambda} = \text{mean time to failure}$$

The series system is the only logic configuration in which components with constant failure rates induce a constant failure rate for the system. In all other configurations, the reliability of the system is not exponential. The system fails at $\min(t_1, t_2, \dots, t_N)$, where t_i is the failure time of the i th component in the system.

The reliability of a parallel system, in which all components are performing the same function so that anyone by itself can successfully carry out the system function, is

$$R(t) = 1 - \prod_{i=1}^N [1 - R_i(t)] \quad (11)$$

Since the system fails when all its components fail, the time to failure of the system is $\max(t_1, t_2, \dots, t_N)$.

More complex logics of system operation, including standby, multistate, etc., require more sophisticated modeling tools like Markov modeling (Zio 2009b) and Monte Carlo simulation (Zio 2013). Both of these methods are capable of accounting for the system behavior as described by its multiple states and the transitions among them. The system states are defined by the states of the units comprising the system. The units are not restricted to having only two possible states

but rather may have a number of different states such as functioning, in standby, degraded, partially failed, completely failed, under maintenance, etc.; the various failure modes of a unit may also be defined as states. The transitions between the states occur randomly in time, because of various mechanisms and activities such as failures, repairs, replacements, and switching operations, which are random in nature. Common cause failures may also be included as possible transitions occurring randomly in time.

Under specified conditions, the stochastic process of the system evolution may be described as a Markov process in which the system states and the possible transitions can be depicted with the aid of a state-space diagram, known as a Markov diagram, and be mathematically described by a probabilistic Markov system of equations. The Markov property states the following: given that a system is in state i at time t , the probability of reaching state j at time $t + v$ does not depend on the states visited by the system prior to t ($0 \leq u < t$): in other words, given the present state of the system, its future behavior is independent of the past.

However, in realistic conditions often the behavior of a system may not respect the Markov property. In these cases, the quantitative analysis may be effectively carried out by Monte Carlo simulation, which corresponds to performing a virtual experiment in which a large number of identical systems, each one behaving differently due to the stochastic character of the system behavior, are simulated during a given time and their failure occurrences are recorded. This, in principle, is the same procedure adopted in the physical (not virtual) reliability tests performed on individual units to estimate their failure rates, mean time to failure, or other parameter characteristics of their failure behavior; the difference is that for units, the tests are actually done physically in laboratory, at reasonable costs and within reasonable testing times (possibly by resorting to accelerated testing techniques, when necessary), whereas for systems this is obviously impracticable for the costs and times

involved in systems failures. Thus, instead of making physical tests on a system, the stochastic process of transition among its states is modeled by defining the probabilistic distribution governing the transition process, and a large number of realizations are generated by sampling from it the times and outcomes of the occurring transitions.

The Monte Carlo simulation of one single system life entails the repeated sampling from the probabilistic distribution of the time of occurrence of the next transition and of the new configuration reached by the system as outcome of the transition, starting from the current system configuration. Then, for the purpose of reliability estimation, a subset of the system configurations is identified as the set of fault states. Whenever the system enters one such configuration, its failure is recorded together with its time of occurrence. With reference to a given time t of interest, an estimate of the probability of system failure before such time, i.e., the system failure probability at time t , can be obtained by the frequency of system failures before t , computed by dividing the number of system life realizations which record a system failure before t by the total number of system life realizations simulated.

Summary

This entry contains some basic concepts, general knowledge, and classical methods for the analysis of the reliability of structures, equipment, and systems and its quantitative estimation. The presentation of the subject matter follows the two phases typically used in practice for the implementation of the analysis: the phase of qualitative analysis for hazards and failure modes identification and the phase of quantitative estimation of the reliability characteristics of interest. The concepts and practices of the first phase are exemplified via the common method of systematic analysis known as the failure mode, effects, and criticality analysis (FMECA). The mathematical, probabilistic concepts necessary

for the second phase of quantification are introduced for individual components and simple system configurations like the series and parallel logics. Also, a qualitative description is provided of advanced methods like Markov modeling and Monte Carlo simulation for the estimation of the reliability characteristics of complex systems.

Introduction

The problem of time variant reliability of randomly parametered nonlinear dynamical systems is formulated. Various analytical and simulation-based strategies to tackle this problem are outlined. Questions on updating reliability models for instrumented structures are also briefly reviewed.

Engineering structures are designed for earthquake loads to display specific forms of inelastic behavior with certain modes of failures preferred over others. The analysis of earthquake response of structures involves transient dynamic analysis which allows for inelastic and geometric nonlinear structural behavior and takes into account uncertainties associated with earthquake-induced loads and structural dynamic properties in the inelastic transient regime. The earthquake-induced ground motions are typically modeled as a vector of non-stationary, Gaussian random processes, which allow for multicomponent and spatial variability characteristics. The uncertain structural properties are often modeled as a vector of mutually dependent non-Gaussian random variables and, in a more realistic framework, as a vector of non-Gaussian random fields evolving in space. When random field models are employed, the random fields are suitably discretized and represented as an equivalent set of random variables. Thus, the governing equation to be studied consists of a set of coupled nonlinear ordinary differential equations with random parameters and random external and (or) parametric excitations. Questions on

reliability measures associated with solution processes here pose significant challenge to the analyst. This entry aims to provide a selective overview of some of the methods and tools to tackle these questions.

Problem Statement

Semi-discretized equations of motion, typically resulting from the application of the finite element method to a structural mechanics problem, of the form

$$\begin{aligned} & \mathbf{M}(\boldsymbol{\theta}) \ddot{\mathbf{Y}}(t) + \mathbf{C}(\boldsymbol{\theta}) \dot{\mathbf{Y}}(t) + \mathbf{K}(\boldsymbol{\theta}) \mathbf{Y}(t) \\ & + \mathbf{Q}[\dot{\mathbf{Y}}(t), \mathbf{Y}(t)] + \bar{\mathbf{Q}}[\dot{\mathbf{Y}}(\tau), \mathbf{Y}(\tau), 0 \leq \tau \leq t] \\ & = \mathbf{F}(t) \mathbf{Y}(0) = \mathbf{Y}_0; \dot{\mathbf{Y}}(0) = \dot{\mathbf{Y}}_0 \end{aligned} \quad (1)$$

are considered. Here a dot represents differentiation with respect to time t ; $\mathbf{Y}(t)$ is a $\bar{d} \times 1$ vector of displacement vector; $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are, respectively, the mass, damping, and stiffness matrices; $\mathbf{Q}$ is a nonlinear function of instantaneous displacement and velocity vectors (arising from geometric nonlinear effects); $\bar{\mathbf{Q}}$ is a nonlinear function of system response time histories up to time t (arising from material nonlinear effects); $\mathbf{F}(t)$ is a vector of external forces; and $\boldsymbol{\theta}$ is a $p \times 1$ vector of system parameters. The forcing vector $\mathbf{F}(t)$ is taken to be a vector of mutually dependent random processes which are not necessarily white, Gaussian, or stationary. The parameter vector $\boldsymbol{\theta}$ encapsulates all the sources of uncertainties arising in specification of structural properties including geometric, mass, stress-strain relations, boundary conditions, and damping characteristics. In general, elements of $\boldsymbol{\theta}$ are modeled as a set of mutually dependent non-Gaussian random variables specified through a p dimensional joint probability density function (PDF) $p_{\boldsymbol{\theta}}(\boldsymbol{\theta})$. Let $h(t) \equiv h[\mathbf{Y}(t), \dot{\mathbf{Y}}(t), \ddot{\mathbf{Y}}(t), \boldsymbol{\theta}]$ be a response metric such that the probability measure $P_S = P\{h[\mathbf{Y}(t), \dot{\mathbf{Y}}(t), \ddot{\mathbf{Y}}(t), \boldsymbol{\theta}] \leq h^* \forall t \in [t_0, t_0 + T]\}$ represents the probability that response metric $h(t)$ stays below the permissible value h^* for all times during the interval

$[t_0, t_0 + T]$. Here P_S is the reliability and its complement $P_F = 1 - P_S$ is the probability of failure.

Remarks

1. The probability of failure here is defined with respect to a specified performance metric $h(t)$ which in general is a non-Gaussian random process.
2. Since the reliability here is defined with respect to permissible values of $h(t)$ over a given time duration $[t_0, t_0 + T]$, the problem of reliability analysis is classified as being time variant.
3. By defining $h_M(\boldsymbol{\theta}) = \max_{t \in [t_0, t_0 + T]} h[\mathbf{Y}(t), \dot{\mathbf{Y}}(t), \ddot{\mathbf{Y}}(t), \boldsymbol{\theta}]$, the maximum of the random process $h(t)$ over the duration $[t_0, t_0 + T]$, the probability of failure can be expressed as $P_F = P[h^* - h_M(\boldsymbol{\theta}) \leq 0] = \langle I[h^* - h_M(\boldsymbol{\theta}) \leq 0] \rangle$. Here $I[h^* - h_M(\boldsymbol{\theta}) \leq 0]$ is the indicator function such that $I[h^* - h_M(\boldsymbol{\theta}) \leq 0] = 1$ if $h^* - h_M(\boldsymbol{\theta}) \leq 0$ and zero otherwise, and $\langle \cdot \rangle$ is the mathematical expectation operator. Expressed in this form, the time variant reliability problem becomes time invariant in nature. This conceptual simplification, however, crucially depends upon the ability to characterize the PDF of $h_M(\boldsymbol{\theta})$ which, in itself, is a challenging problem.
4. The nature of the problem gets simplified if randomness is present only in specifying external excitations $\mathbf{F}(t)$ or only in specifying system parameters $\boldsymbol{\theta}$.
5. Problems of time variant system reliability, which involve more than one performance metric, can also be formulated, but their study is far more involved.

Exact solutions to the problem of determining P_F are not available for most cases of practical interest. One takes recourse to approximate analytical solutions or to Monte Carlo simulation-based methods. The analytical methods can be broadly classified into those based on level crossing statistics and those based on Markovian property of system responses. The simulation-based methods typically employ suitable strategies to control the sampling variance. A discussion of these topics forms the subject of the following sections.

Methods Based on Level Crossing Statistics

Introducing a counting process, where $N(h^*, 0, T)$ = the number of times the process $h(t)$ crosses level h^* during the interval $[0, T]$, and a random variable $T_f(h^*)$ = time taken by $h(t)$ to cross level h^* for the first time with $t \geq 0$, it can be shown that (Nigam 1983; Soong and Grigoriu 1993)

$$N(h^*, 0, T) = \int_0^T |\dot{h}(t)| \delta[h(t) - h^*] dt \quad (2)$$

It follows that $P[T_f(h^*) \geq t] = P[N(h^*, 0, t) = 0]$. Here it is assumed that at $t = 0$, the structure lies in the safe region. Furthermore, the random variable $h_M = \max_{t \in [0, T]} h(t)$ can be characterized using the relation $P[h_M \leq h^*] = P[T_f(h^*) \geq T]$. Thus the key to the determination of the reliability $1 - P_F = P[h_M \leq h^*]$ lies in the characterization of the counting process $N(h^*, 0, T)$. If h^* is taken to be large, such that, crossing of h^* by $h(t)$ can be considered as rare, $N(h^*, 0, T)$ can be approximated to be a Poisson random variable (see, Leadbetter et al. 1983, for the details of theoretical basis for this approximation) leading to

$$P[N(h^*, 0, T) = n] = \exp(-\lambda T) \frac{(\lambda T)^n}{n!}; \quad (3)$$

$$n = 0, 1, 2, \dots, \infty$$

Here the parameter λ is the average rate of crossing of level h^* given by

$$\lambda = \int_{-\infty}^{\infty} |\dot{h}| p_{h\dot{h}}(h^*, h; t) d\dot{h} \text{ which, for a stationary}$$

Gaussian random process, is given by $\lambda = \frac{\sigma_{\dot{h}}}{\pi \sigma_h} \exp\left\{-\frac{1}{2} \frac{h^{*2}}{\sigma_h^2}\right\}$ where σ_h and $\sigma_{\dot{h}}$ are, respectively, the steady-state variance of $h(t)$ and $\dot{h}(t)$. For more general class of models for $h(t)$, the evaluation of λ requires the knowledge of joint PDF of $h(t)$ and $\dot{h}(t)$. When $N(h^*, 0, T)$ is modeled as a Poisson random variable, the first passage time $T_f(h^*)$ gets distributed

exponentially and a Gumbel model for h_M can be further deduced from this. Several refinements to this basic idea are available in the literature (Nigam 1983; Soong and Grigoriu 1993): these involve development of one-step memory models for the counting process $N(h^*, 0, T)$ and models using envelope processes of $h(t)$.

Markov Vector Methods

When $F(t)$ arises as a vector of Gaussian white noise process or as a vector of filtered white noise processes, it becomes advantageous to interpret Eq. 1 as an Ito's stochastic differential equation (SDE) and represent it as

$$dX(t) = A[X(t), \Theta, t]dt + D[X(t), \Theta, t]dB(t)$$

$$X(0) = X_0 \quad (4)$$

Here $X(t)$ is the $d \times 1$ vector, A is the $d \times 1$ drift vector, D is the $d \times q$ diffusion matrix, and $dB(t)$ is a $q \times 1$ vector of increments of Brownian motion processes with $\langle dB(t) \rangle = 0$ and $\langle dB(t) dB^T(t + \tau) \rangle = \Sigma(t) \delta(\tau)$. The vector $X(t)$ not only includes displacement and velocity vectors [i.e., $Y(t)$ and $\dot{Y}(t)$] but also contains additional states arising in representation of hysteretic nonlinearities through internal variables and states appearing in representing applied excitations as filtered white noise processes. Box 1 illustrates the deduction of the governing equation in the above form for a single degree of freedom (SDOF) system with hysteretic nonlinearity and filtered white noise random excitation. Considering the vector of system parameters, Θ , to be deterministic, it can be shown that the response vector $X(t)$ possesses the Markovian property (Lin and Cai 1995). Such a process is completely described by the transition PDF $p(x; t|x_0; t_0)$ and the initial PDF $p(x_0; t_0)$. Associated with the governing SDE, one can derive equations governing the time evolution of the transitional PDF, $p(x, t|x_0, t_0)$. These equations can take three alternative forms, namely, the form of an integral equation

Box 1: Bouc–Wen Hysteretic SDOF System Under Kanai–Tajimi–Clough–Penzien Earthquake Excitation

$$\begin{aligned}
 & \ddot{y}_s + 2\eta_s \omega_s \dot{y}_s \\
 & + \omega_s^2 y_s = e(t)w(t)\ddot{y}_f \\
 & + 2\eta_f \omega_f \dot{y}_f + \omega_f^2 y_f \\
 & = 2\eta_s \omega_s \dot{y}_s + \omega_s^2 y_s \ddot{y} \\
 & + 2\eta \omega \dot{y} + \alpha y + (1 - \alpha) \bar{q} \\
 & = \ddot{y}_f \bar{q} = -\gamma |\dot{y}| \bar{q} |\bar{q}|^{v-1} \\
 & - \beta |\dot{y}| \bar{q}|^v + A \ddot{y}_s(0) = y_{s0}, \\
 & \dot{y}_s(0) = \dot{y}_{s0}, y_f(0) = y_{f0}, \\
 & \dot{y}_f(0) = \dot{y}_{f0}, y(0) = y_0, \\
 & \dot{y}(0) = \dot{y}_0
 \end{aligned}$$

Here $w(t)$ is modeled as a zero-mean white noise excitation with autocovariance $\langle w(t)w(t+\tau) \rangle = \sigma^2 \delta(\tau)$, $e(t) = A_0(e^{-\alpha_1 t} - e^{-\alpha_2 t})$ is a deterministic envelope function which imparts non-stationarity to the input at the bed rock level, and ω and η are the system parameters. The subscripts s and f denote, respectively, the parameters of the Kanai–Tajimi model and the Clough–Penzien high-pass filter. The parameters α , β , A , v and γ characterize the inelastic properties of the oscillator.

 \end{aligned}$$

(continued)

$$dX(t) = \mathbf{A}_1(\boldsymbol{\Theta})X(t) + \mathbf{A}[X(t), \boldsymbol{\Theta}, t]dt + \mathbf{D}(t)dB(t)$$

$$\text{with } \mathbf{X} = (x_s, \dot{x}_s, x_f, \dot{x}_f, x, \dot{x}, \bar{q})^t; \boldsymbol{\Theta} = (\omega_s, \eta_s, \omega_f, \eta_f, \omega, \eta)^t \sim p_{\boldsymbol{\Theta}}(\boldsymbol{\Theta})$$

$$\mathbf{A}_1 = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ -\omega_s^2 & -2\eta_s\omega_s & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ \omega_s^2 & 2\eta_s\omega_s & -\omega_f^2 & -2\eta_f\omega_f & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ \omega_s^2 & 2\eta_s\omega_s & -\omega_f^2 & -2\eta_f\omega_f & \alpha & -2\eta\omega & (1-\alpha) \\ 0 & 0 & 0 & 0 & 0 & 0 & A \end{bmatrix}; \mathbf{A} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \\ -\gamma|x_6|x_7|x_7|^{v-1} - \beta x_6|x_7|^v \end{bmatrix}; \mathbf{D} = \begin{bmatrix} 0 \\ e(t) \\ 0 \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix}$$

(in which case it is called the Chapman–Kolmogorov–Smoluchowski equation), a diffusion type of partial differential equation with $\mathbf{x}$ and t as independent variables (in which case it is called the forward Kolmogorov equation or the Fokker–Planck–Kolmogorov equation), and a diffusion type of partial differential equation with $\mathbf{x}_0$ and t_0 as independent variables (in which case it is called the Kolmogorov backward equation). Furthermore, the governing equation for the survival function, $R(t|\mathbf{x}_0, t_0)$ = probability that the time for response originating at $\mathbf{x}_0$ at t_0 to cross a critical threshold is greater than t , also satisfies the operation appearing in the

Kolmogorov backward equation. These equations are listed below.

1. Chapman–Kolmogorov–Smoluchowski equation:

$$p(\mathbf{x}; t|\mathbf{x}_0; t_0) = \int p(\mathbf{x}; t|\bar{\mathbf{x}}; \tau) p(\bar{\mathbf{x}}; \tau|\mathbf{x}_0; t_0) d\bar{\mathbf{x}} \\ \forall t_0 < \tau < t$$

This is the consistency condition that the transition PDF needs to satisfy so as to ensure that $\mathbf{X}(t)$ is a Markov vector.

2. Fokker–Planck–Kolmogorov equation:

$$\frac{\partial}{\partial t} p(\mathbf{x}; t|\mathbf{x}_0; t_0) = - \sum_{i=1}^d \frac{\partial}{\partial x_i} \{p(\mathbf{x}; t|\mathbf{x}_0; t_0) A_i(\mathbf{x}, t)\} + \frac{1}{2} \sum_{i=1}^d \sum_{j=1}^d \frac{\partial^2}{\partial x_i \partial x_j} \left\{ p(\mathbf{x}; t|\mathbf{x}_0; t_0) [\mathbf{D}(\mathbf{x}, t) \boldsymbol{\Sigma} \mathbf{D}^t(\mathbf{x}, t)]_{ij} \right\} \\ p(\mathbf{x}; t_0|\mathbf{x}_0, t_0) = \delta(\mathbf{x} - \mathbf{x}_0) = \prod_{i=1}^d (x_i - x_{0i}); \lim_{x_i \rightarrow \infty} p(\mathbf{x}; t|\mathbf{x}_0, t_0) \rightarrow 0, i = 1, 2, \dots, d$$

3. Kolmogorov backward equation:

$$\frac{\partial}{\partial t_0} p(\mathbf{x}; t|\mathbf{x}_0; t_0) = - \sum_{i=1}^d A_i(\mathbf{x}_0, t_0) \frac{\partial}{\partial x_{0i}} \{p(\mathbf{x}; t|\mathbf{x}_0; t_0)\} - \frac{1}{2} \sum_{i=1}^d \sum_{j=1}^d [\mathbf{D}(\mathbf{x}_0, t_0) \boldsymbol{\Sigma} \mathbf{D}^t(\mathbf{x}_0, t_0)]_{ij} \frac{\partial^2}{\partial x_{0i} \partial x_{0j}} [p(\mathbf{x}; t|\mathbf{x}_0; t_0)] \\ p(\mathbf{x}; t_0|\mathbf{x}_0, t_0) = \delta(\mathbf{x} - \mathbf{x}_0) = \prod_{i=1}^d (x_i - x_{0i}); \lim_{x_i \rightarrow \infty} p(\mathbf{x}; t|\mathbf{x}_0, t_0) \rightarrow 0, i = 1, 2, \dots, d$$

4. Kolmogorov backward equation for survival time:

Let $R(t|\mathbf{x}_0; t_0)$ denote the probability that the response of interest, $\mathbf{X}(t)$, starting from the safe

region Ω , takes time $\mathcal{T}$ to cross the boundary $\partial\Omega$ for the first time. Then, $R(t|\mathbf{x}_0; t_0) = P[\mathcal{T} > (t - t_0) | \mathbf{X}(t_0) = \mathbf{x}_0]$ and satisfies the Kolmogorov backward equation given by

$$\frac{\partial}{\partial t_0} R(t|\mathbf{x}_0; t_0) = -\sum_{i=1}^d A_i(\mathbf{x}_0, t_0) \frac{\partial}{\partial x_{0i}} [R(t|\mathbf{x}_0; t_0)] - \frac{1}{2} \sum_{i=1}^d \sum_{j=1}^d [\mathbf{D}(\mathbf{x}_0, t_0) \mathbf{\Sigma} \mathbf{D}'(\mathbf{x}_0, t_0)]_{ij} \frac{\partial^2}{\partial x_{0i} \partial x_{0j}} [R(t|\mathbf{x}_0; t_0)]$$

$$R(t_0|\mathbf{x}_0; t_0) = 1 \text{ if } \mathbf{x}_0 \in \partial\Omega; R(t|\mathbf{x}_0; t_0) = \begin{cases} 0, & \text{if } \mathbf{x}_0 \in \partial\Omega \\ 1, & \text{if } \mathbf{x}_0, \mathbf{x}(t) \in \Omega \end{cases}$$

5. Equation governing moments of function of $\mathbf{X}(t)$:

$$\frac{\partial}{\partial t} \langle \psi(\mathbf{X}, t) \rangle = \sum_{i=1}^d \left\langle A_i(\mathbf{X}, t) \frac{\partial}{\partial x_{0i}} \psi(\mathbf{X}; t) \right\rangle + \frac{1}{2} \sum_{i=1}^d \sum_{j=1}^d \left\langle [\mathbf{D}(\mathbf{X}, t) \mathbf{\Sigma} \mathbf{D}'(\mathbf{X}, t)]_{ij} \frac{\partial^2}{\partial x_{0i} \partial x_{0j}} \psi(\mathbf{X}, t) \right\rangle + \left\langle \frac{\partial}{\partial t} \psi(\mathbf{X}, t) \right\rangle$$

$$\langle \psi(\mathbf{X}, 0) \rangle = \psi_0$$

If one considers moments of the form $\langle X_1^{n_1}(t) X_2^{n_2}(t) \cdots X_m^{n_m}(t) \rangle$, it can be shown that, for linear systems, the moment equations form a closed set of equations and can be solved at least numerically. For nonlinear systems, however, the moment equations form an infinite hierarchy of equations which at no stage provide sufficient number of equations to solve for the moments. This limits the

applicability of the moment equations for such systems.

6. Equation governing moments of first passage time:

The PDF of the survival time $\mathcal{T}$ can be obtained as $p_{\mathcal{T}}(t) = \frac{d}{dt} [1 - R(t|\mathbf{x}_0, t_0)]$. Accordingly, the governing equations for moments of first passage time, $m_l = \langle \mathcal{T}^l \rangle$, $l = 1, 2, \dots$, are given by

$$(l+1)m_l - \sum_{i=1}^d A_i(\mathbf{x}_0, t_0) \frac{\partial m_{l+1}}{\partial x_{0i}} - \frac{1}{2} \sum_{i=1}^d \sum_{j=1}^d [\mathbf{D}(\mathbf{x}, t) \mathbf{\Sigma} \mathbf{D}'(\mathbf{x}, t)]_{ij} \frac{\partial^2 m_{l+1}}{\partial x_{0i} \partial x_{0j}}; l = 1, 2, \dots$$

$$m_1 = 1; m_{l+1} = \begin{cases} 0, & \text{if } \mathbf{x}_0 \in \partial\Omega \\ < \infty, & \text{if } \mathbf{x}_0 \in \Omega \end{cases}$$

Table 1 lists a few cases in which exact solutions for some of the above equations can be obtained. It may be noted that the determination of $p(\mathbf{x}, t|\mathbf{x}_0, t_0)$ can, in principle, facilitate the determination of the joint PDF $p_{h\dot{h}}(h^*, \dot{h}^*; t)$ and, hence, to the subsequent determination of the probability $P[h_M \leq h^*] = P[T_f(h^*) \geq T]$.

Monte Carlo Simulation Methods

The main idea here is to obtain, on a computer, random samples of $\boldsymbol{\Theta}$ and $d\mathbf{B}(t)$ compatible with the prescribed joint PDF and estimate the probability of failure as

$$\hat{P}_F = \frac{1}{N_1} \sum_{i=1}^{N_1} I[h^* - h_M^i(\boldsymbol{\Theta}) \leq 0] \quad (5)$$

Here $h_M^i(\boldsymbol{\Theta})$ is the maximum value of the response metric of interest corresponding to the i^{th} realizations of $\boldsymbol{\Theta}$ and $d\mathbf{B}(t)$, and N_1 is the sample size. This calculation is facilitated by discretizing Eq. 4 to obtain

$$\mathbf{x}_{k+1} = \boldsymbol{\phi}_k(\mathbf{x}_k, \boldsymbol{\theta}, \mathbf{v}_k); \mathbf{x}_0 = \mathbf{X}_0 \quad (6)$$

Here $\mathbf{x}_k$, $\boldsymbol{\phi}_k$ are $r \times 1$ vectors, $\mathbf{v}_k$ is $n_v \times 1$ vector of Gaussian random variables, and $k = 0, 1, 2, \dots, N$ represents the discretized

Reliability Estimation and Analysis for Dynamical Systems, Table 1 Few dynamical systems for which exact solutions can be obtained through the Markov vector approach

S. no.	System	Example	Quantities which are exactly determinable
1	Linear time invariant systems under external white noise or filtered white noise excitations (Nigam 1983)	$\ddot{u} + 2\eta\omega\dot{u} + \omega^2u = f(t)$ $\dot{f} + 2\eta_1\omega_1\dot{f} + \omega_1^2f = w(t)$ $u(0) = u_0, \dot{u}(0) = \dot{u}_0; f(0) = f_0, \dot{f}(0) = \dot{f}_0$ $\mathbf{x} = (u, \dot{u}, f, \dot{f})^t$	$p(\mathbf{x}; t)$ $p(\mathbf{x}; t \mathbf{x}_0; t_0)$ $\langle x_1^m(t) x_2^n(t) \cdots \rangle$ $\forall t$
2	Linear time invariant systems under parametric and (or) external white noise excitations (Soong 1973)	$\ddot{u} + 2\eta\omega\dot{u}[1 + w_1(t)] + \omega^2u[1 + w_2(t)] = w_3(t)$ $u(0) = u_0, \dot{u}(0) = \dot{u}_0$ $\mathbf{x} = (u, \dot{u})^t$	Time evolution of $\langle x_1^m(t) x_2^n(t) \rangle$ moments by solving a closed set of moment equations for all t
3	Nonlinear SDOF systems with nonlinear damping and (or) stiffness properties under external and white noise excitations (Caughey and Payne 1967; Lin and Cai 1995)	$\ddot{u} + 2\eta\omega\dot{u} + \omega^2u + f(u) = w(t)$ $u(0) = u_0, \dot{u}(0) = \dot{u}_0, \mathbf{x} = (u, \dot{u})^t$ $\ddot{u} + (\alpha + \beta u^2)\dot{u} + \omega^2[1 + w_1(t)]u = w_2(t)$ $u(0) = u_0, \dot{u}(0) = \dot{u}_0, \mathbf{x} = (u, \dot{u})^t$	$\lim_{t \rightarrow \infty} p(\mathbf{x}; t \mathbf{x}_0; t_0)$
4	A class of nonlinear multi-degree of freedom systems under combined parametric and external white noise excitation (Lin and Cai 1995)	$\ddot{u}_i + h_i(u, \dot{u}) = g_{ij}(u, \dot{u})w_j(t)$ $i = 1, 2, \dots, N_x; j = 1, 2, \dots, m;$ $\mathbf{x} = (u_1, \dot{u}_1, \dots, u_n, \dot{u}_n)^t$ $\ddot{u}_1 + \pi\mu(K_{11}\dot{u}_1 + 2\beta K_{12}\dot{u}_2)$ $\quad + \frac{\partial}{\partial u_1}H(u_1, u_2) = w_1(t)$ $\ddot{u}_2 + \pi\mu[2(1 - \beta)K_{12}\dot{u}_1 + K_{22}\dot{u}_2]$ $\quad + \frac{\partial}{\partial u_2}H(u_1, u_2) = w_2(t)$ $\langle w_i(t)w_j^T(t + \tau) \rangle = 2\pi K_{ij}\delta(\tau); i, j = 1, 2$ $\mathbf{x} = (u_1, \dot{u}_1, u_2, \dot{u}_2)^t$	$\lim_{t \rightarrow \infty} p(\mathbf{x}; t \mathbf{x}_0; t_0)$

time instants such that $t_k = k\Delta t$ and $N\Delta t = T$ with $\mathbf{x}_k$ serving as a discrete approximation to the response vector $\mathbf{X}(t)$ at $t = t_k$. Methods for discretization of SDEs are extensively described in the book by Kloeden and Platen (1992). Introducing a performance function $G(\boldsymbol{\theta}, \mathbf{v}) = h^* - \max_{0 \leq k \leq N} h[\boldsymbol{\theta}, \mathbf{x}_k]$, where $\mathbf{v} = (\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_N)$, the failure probability is obtained as $P_F = P[G(\boldsymbol{\theta}, \mathbf{v}) \leq 0]$. Accordingly, the estimator $\hat{P}_F$ is deduced to be given by

$$\hat{P}_F = \frac{1}{N_1} \sum_{i=1}^{N_1} I[G(\boldsymbol{\theta}^i, \mathbf{v}^i) \leq 0] \quad (7)$$

It can be shown that $\hat{P}_F$ is an unbiased and consistent estimator of the probability of failure with minimum variance for a specified N_1 . Furthermore, the sampling variance here is given

by $\text{Var}(\hat{P}_F) = P_F(1 - P_F)/N_1$. Accordingly, an increase in sample size N_1 is needed to reduce the sampling variance. The accuracy of the estimate obtained is quantified through its coefficient of variation defined as $\delta = \sqrt{(1 - P_F)/(N_1 P_F)}$. Thus, for instance, for $P_F = 10^{-5}$, and a target value of δ of 5 %, one needs about 4×10^7 samples to estimate P_F . The requirement on the number of samples increases to about 10^9 when δ is limited to 1 %. Given that the evaluation of $G(\boldsymbol{\theta}^i, \mathbf{v}^i)$, for each i , typically requires the execution of a finite element code, the evaluation of P_F using Eq. 7 is still not practically feasible. A way forward here is to devise an estimator for P_F in which the sampling variance can be controlled without taking recourse to increase in sample size. This class of methods is broadly termed as variance reduction methods and has been widely studied in the existing literature. The main idea here is to utilize known information

about the model to improve on the performance of the estimator. A few of the developments in this context, in the area of time variant structural reliability modeling, are outlined in the following sections.

Importance Sampling

To simplify the formulation, the basic random variables $(\boldsymbol{\theta}, \mathbf{v})$ are transformed into space of standard normal random variables denoted by $\mathbf{U} = (\mathbf{U}_{\boldsymbol{\theta}}, \mathbf{U}_{\mathbf{v}})$ where $\mathbf{U}_{\boldsymbol{\theta}}$ and $\mathbf{U}_{\mathbf{v}}$ are the vectors of standard normal random variables originating from $\boldsymbol{\theta}$ and $\mathbf{v}$, respectively, with the understanding that the transformations $\boldsymbol{\theta} = T_{\boldsymbol{\theta}}(\mathbf{U}_{\boldsymbol{\theta}})$ and $\mathbf{v} = T_{\mathbf{v}}(\mathbf{U}_{\mathbf{v}})$ exist (Melchers 1999). The performance function in terms of the standard normal variable vector $\mathbf{U}$ is denoted by $G(\mathbf{U}) = h^* - \max_{0 \leq k \leq N} \underline{h}(\mathbf{U}_{\boldsymbol{\theta}}, \mathbf{x}_k)$ where $\underline{h}(\mathbf{U}_{\boldsymbol{\theta}}, \mathbf{x}_k) = h[T_{\boldsymbol{\theta}}(\mathbf{U}_{\boldsymbol{\theta}}), \mathbf{x}_k]$, $k = 0, 1, \dots, N$. Instead of drawing samples from $p_{\mathbf{U}}(\mathbf{u})$, one could also select an importance sampling PDF $\pi_{\mathbf{U}}(\mathbf{u})$ and evaluate P_F using $P_F = \int_{-\infty}^{\infty} I[G(\mathbf{u}) \leq 0] \frac{p_{\mathbf{U}}(\mathbf{u})}{\pi_{\mathbf{U}}(\mathbf{u})} \pi_{\mathbf{U}}(\mathbf{u}) d\mathbf{u}$. The estimator $\hat{P}_F$ can now be modified to read as

$$\hat{P}_F^{IS} = \frac{1}{N_2} \sum_{i=1}^{N_2} \frac{p_{\mathbf{U}}(\mathbf{u}^i)}{\pi_{\mathbf{U}}(\mathbf{u}^i)} I[G(\mathbf{u}^i) \leq 0] \quad (8)$$

Here $\mathbf{u}^i$, $i = 1, 2, \dots, N_2$ are random samples drawn from $\pi_{\mathbf{U}}(\mathbf{u})$. It can be shown that the above estimator for P_F is unbiased and has the sampling variance given by

$$\text{Var}(\hat{P}_F) = \left\langle \left\{ I[G(\mathbf{U}) \leq 0] \frac{p_{\mathbf{U}}(\mathbf{U})}{\pi_{\mathbf{U}}(\mathbf{U})} - P_F \right\}^2 \right\rangle \quad (9)$$

The yet undetermined $\pi_{\mathbf{U}}(\mathbf{u})$ is now chosen such that the above sampling variance is minimized. It can be verified that for $\pi_{\mathbf{U}}(\mathbf{u}) = I[G(\mathbf{u}) \leq 0] p_{\mathbf{U}}(\mathbf{u}) / P_F$, the sampling variance becomes zero. This PDF is known as the ideal importance sampling PDF (ISPDF). As is evident, the determination of this ideal ISPDF

requires the prior knowledge of P_F , the very quantity that is deemed as unknown in the first place. This obviously indicates the limitation on the utility of ideal ISPDF to actually determine P_F . On the other hand, the significance of ideal ISPDF lies in the fact that it actually exists, and one could aim to construct suboptimal ISPDF which substantially reduces the sampling variance below that of the brute force Monte Carlo simulations. Thus, for example, the ISPDF could be obtained in standard normal space as a multivariate Gaussian PDF with mean placed at the design point (Schueller and Stix 1987) which has been found through a prior step based on the first-order reliability method (Melchers 1999).

Subset Simulation

The main idea here is to represent the failure region, Ψ , as a limit of decreasing sequence of failure events, Ψ_i , $i = 1, 2, \dots, M$, such that $\Psi_1 \supset \Psi_2 \supset \dots \supset \Psi_M = \Psi$ and $\Psi_k = \bigcap_{i=1}^k \Psi_i$, $k = 2, \dots, M$, so that the failure probability can be expressed as $P_F = P(\Psi_1) \prod_{i=1}^{M-1} P(\Psi_{i+1} | \Psi_i)$ (Au and Beck 2001). The simulation effort is focused on delineating the regions Ψ_i , $i = 1, 2, \dots, M$ and in estimating the probabilities $P(\Psi_1)$ and $P(\Psi_{i+1} | \Psi_i)$, $i = 1, 2, \dots, M - 1$. The effectiveness of the method is due to the fact that each of these probabilities is much larger than P_F and hence can be estimated reliably with fewer samples. Sampling strategies based on the application of Markov Chain Monte Carlo method have been adopted in this context. Here the conditional simulation is carried out using a modified version of the Metropolis Hastings algorithm.

Trajectory Splitting Methods

By considering the parameter vector, $\boldsymbol{\theta}$, to be a deterministic quantity, Eq. 4 can now be rewritten in a simpler form as

$$\begin{aligned} d\mathbf{X}(t) &= \mathbf{A}[\mathbf{X}(t), t] dt \\ &\quad + \mathbf{D}[\mathbf{X}(t), t] d\mathbf{B}(t); \mathbf{X}(0) \\ &= \mathbf{X}_0 \end{aligned} \quad (10)$$

The probability of failure is obtained as

$$P_F = P\left\{h^* - \max_{0 \leq t \leq T} h[X(t), t] \leq 0\right\} \\ = \left\langle I\left(h^* - \max_{0 \leq t \leq T} h[X(t), t] \leq 0\right) \right\rangle \quad (11)$$

The trajectory splitting methods are a class of methods that are based on driving response trajectories in state-space toward failure regions. The idea here is to associate with each trajectory a weight, and judge each of the trajectories by their proximity to the failure region.

For the purpose of illustration, consider the response of interest to be denoted by $Y(t)$. An approximation to the cumulative distribution function (CDF) of this response quantity, denoted by $P(y; t) = P[Y(t) \leq y]$, is written as

$$P(y; t) = \sum_{i=1}^{N_{dc}} I[Y^i(t) \leq y] W^i(t) \quad (12)$$

Here $Y^i(t)$, $i = 1, 2, \dots, N_{dc}$ are a set of sample realizations of the random process $Y(t)$, which is governed by an SDE of the form given in Eq. 10, and the weights $W^i(t)$, $i = 1, 2, \dots, N_{dc}$ have the following properties:

$$W^i(t) \geq 0, \quad \sum_{i=1}^{N_{dc}} W^i(t) = 1 \quad (13)$$

Furthermore, at any time instant t , the importance of each sample realization is quantified in terms of a heuristic energy term, $C^i(t) = [E_{PE}^i(t) + E_{KE}^i(t)] P_e(t) W^i(t)^{\bar{\beta}}$. Here $E_{PE}^i(t)$ is the potential energy, $E_{KE}^i(t)$ is the kinetic energy of the system, $P_e(t) = F(t)^T \dot{Y}(t)$ is the input power of the external excitation where $F(t)$ is the external force, $\dot{Y}(t)$ is the velocity of the response, and $\bar{\beta}$ is an importance parameter with $0.1 \leq \bar{\beta} \leq 0.5$.

In the double and clump method (Pradlwarter and Schueller 1999), the splitting of the most

favorable trajectories is accompanied by clumping of the least favored samples. Trajectories whose energy, $C(t)$, is estimated to be high are replicated, and the trajectories with lesser energy are clumped together. In every case, the interference with ensemble of samples is accompanied by suitable adjustment of associated weights so that the estimator under consideration remains unbiased.

In the Russian roulette and splitting method (Pradlwarter and Schueller 1999), the least favored trajectories are eliminated from further evolution, and those trajectories which evolve toward the failure region are split and multiplied thereby enhancing the number of samples moving toward the failure region. Here, every realization, $Y^i(t)$, $i = 1, 2, \dots, N_{dc}$, is allowed to take part in further simulations with a probability $p^i(t)$ and cease to exist with probability $1 - p^i(t)$. The expression for the CDF, given in Eq. 12, is modified by considering the additional survival probability terms as

$$P(y; t) = \sum_{i=1}^{N_{dc}} I[Y^i(t) \leq y] J^i(t) \bar{W}^i(t) \quad (14)$$

Here $J^i(t)$, $i = 1, 2, \dots, N_{dc}$ is a Bernoulli random variable such that $P[J^i(t) = 1] = p^i(t)$ and $P[J^i(t) = 0] = 1 - p^i(t)$, and $\bar{W}^i(t)$, $i = 1, 2, \dots, N_{dc}$ denote the weights after implementing the Russian roulette and are taken to be given by $W^i(t)/p^i(t)$ so that the estimator given in Eq. 14 remains unbiased. Also, the survival probability $p^i(t)$ is taken to be proportional to the quantity $1 - \{[C_m(t) - C^i(t)]/C_m(t)\}^2$ where $C_m(t) = \max_{1 \leq i \leq N_{dc}} C^i(t)$.

The selection of the importance descriptor, $C(t)$, based on the notion of distance between samples led to the development of a method called distance-controlled Monte Carlo simulation (Pradlwarter and Schueller 1999). Here the trajectories are further manipulated using the Russian roulette with splitting strategy so as to make the realizations to be uniformly distributed in space.

Some variants of the subset simulation method, which are based on splitting of trajectories, are as follows:

1. Subset simulation with splitting (Ching et al. 2005a): The trajectories here, after reaching the intermediate threshold level, are split into offsprings from the time instant they reach the intermediate threshold value, thus resulting in the new trajectories which always lie in the conditional failure region. This can be explained as follows:

Let t_m be the time instant when a trajectory $x(t)$ reaches the intermediate threshold level, α . This time history is represented as $x(t) = x^-(t)$ for $t \leq t_m$, and $x(t) = x^+(t)$ for $t > t_m$. The corresponding excitations are denoted by $u^-(t)$ and $u^+(t)$, respectively. According to the splitting algorithm, a response trajectory, $\tilde{x}(t)$, always lie in the intermediate failure region, provided the excitation is given as $\tilde{u}(t) = [u^-(t), \tilde{u}^+(t)]$. Here $\tilde{u}^+(t)$, $t > t_m$ is generated using Monte Carlo simulation according to the PDF $p[u^+(t)|u^-(t)] = p[u^+(t), u^-(t)]/p[u^-(t)]$.

2. The advantages of the original subset simulation (Au and Beck 2001) and subset simulation with splitting (Ching et al. 2005a) have been combined to result in a new methodology known as hybrid subset simulation (Ching et al. 2005b). Here the original subset simulation is made use of till the trajectories reach the intermediate threshold levels, and there onwards the splitting algorithms takes over.

The Girsanov Transformation-Based Variance Reduction Technique

In simulation studies on Markovian systems governed by Ito's SDEs of the form given in Eq. 10, an artificial control force can be introduced into the governing equation so as to achieve reduction in Monte Carlo sampling variance associated with desired response statistics (Kloeden and Platen 1992). The process of replacing a given SDE by a modified equation with artificial controls in this context is called the Girsanov transformation. The control force and

the estimators are formulated so that the estimate remains unbiased while at the same time striving to reduce the sampling variance. To illustrate this, consider the modified version of the SDE given in Eq. 10,

$$\begin{aligned} d\tilde{X}(t) &= A[\tilde{X}(t), t]dt + D[\tilde{X}(t), t]u(t)dt \\ &\quad + D[\tilde{X}(t), t]dB(t)d\Gamma(t) \\ &= -\Gamma(t)u'(t)dB(t)\tilde{X}(0) \\ &= X_0, \Gamma(0) = \Gamma_0 \end{aligned} \quad (15)$$

Here $u(t)$ is the additional control force, $\Gamma(t)$ is a scalar correction term introduced to account for the addition of controls, Γ_0 is the initial condition on $\Gamma(t)$ which can be taken to be deterministic, and $\tilde{X}(t)$ is the biased state corresponding to the modified excitation $D[\tilde{X}(t), t]u(t) + D[\tilde{X}(t), t]dB(t)$. It can be shown that (Grigoriu 2002; Macke and Bucher 2003)

$$\begin{aligned} &\left\langle I\left(h^* - \max_{0 \leq t \leq T} h[X(t)] \leq 0\right) \right\rangle \\ &= \left\langle \Gamma(T)I\left(h^* - \max_{0 \leq t \leq T} h[\tilde{X}(t)] \leq 0\right) \right\rangle / \Gamma_0 \end{aligned} \quad (16)$$

Here Γ_0 has been taken to be deterministic. An estimator for evaluating the expression on the right hand side can be obtained as

$$\tilde{P}_F = \frac{1}{N_2 \Gamma_0} \sum_{i=1}^{N_2} \Gamma(T) I\left\{h^* - \max_{0 \leq t \leq T} h[\tilde{X}^i(t), t] \leq 0\right\} \quad (17)$$

where $\tilde{X}^i(t)$ are random draws from Eq. 15. It follows that $\langle \tilde{P}_F \rangle = P_F$ and $\text{Var}(\tilde{P}_F)$ will be dependent on N_2 and the yet to be determined control vector $u(t)$. The control $u(t)$ is now selected such that $\text{Var}(\tilde{P}_F) \ll \text{Var}(\hat{P}_F)$. It can be shown that an ideal control $u^*(t)$ exists which yields $\text{Var}(\tilde{P}_F) = 0$, but its construction requires the knowledge of P_F , the very quantity being sought to be determined. The way forward would be to seek a suboptimal control $u(t)$ which helps to reduce the sampling variance

appreciably and not to seek the ideal situation of obtaining $\text{Var}(\hat{P}_F) = 0$. Here an associated dynamical system

$$\begin{aligned} dV(t) &= A[V(t), t]dt + D[V(t), t]u(t)dt; 0 \leq t \leq T \\ V(0) &= X_0 \end{aligned} \quad (18)$$

is considered. The control $u(t)$ is determined such that it minimizes the distance function given by

$$\beta(\tau^m) = \sqrt{\sum_{j=1}^q \int_0^{\tau^m} u_j^2(t)dt} \text{ subject to the constraint } h^* - h[V(\tau^m)] = 0 \text{ with } 0 < \tau^m \leq T.$$

For linear systems and linear performance functions, the suboptimal control force can be obtained as a function of impulse response functions reversed in time. Also from Eq. 15, it can be noted that the evaluation of the correction process, also known as the Radon–Nikodym derivative, is independent of the mathematical model for the structure under study. Thus, an acceptable choice for the control force can be made solely based on experimental techniques, and the estimator for the reliability can be deduced without taking further recourse to mathematical model for the structure under study. This permits the application of the Girsanov transformation-based variance reduction technique in the experimental study of time variant reliability of complex structural systems which are difficult to model mathematically (Sundar and Manohar 2014a).

Different variance reduction strategies can be combined into a single framework so as to leverage advantages associated with each one of them. Thus, for example, the subset simulation method and the Girsanov transformation-based method can be combined in such a way that subset simulations handle the uncertainties associated with parameters, and the Girsanov transformation takes care of the random excitations (Sundar and Manohar 2014b). Performance of few simulation-based variance reduction techniques with respect to few benchmark problems has been documented by Schueller and Pradlwarter (2007).

System Reliability

Structural systems typically consist of several components and are liable to fail in more than one way due to the failure of all or some of the components. Reliability analysis of such systems is carried out by defining a performance function corresponding to each failure element and identifying the possible modes that lead to the failure of the system as a whole. Unlike the performance function considered in the preceding sections, the performance indicators to vector-valued functions present a more realistic case whereby the failure of the system can be modeled by series systems (weakest link), parallel systems (exceedance of all the limit states), or more generally a combination of both. In the time-dependent reliability framework, it leads to the outcrossing problem of the vector-valued stochastic process whose elements are the performance functions.

To illustrate this, consider the performance metrics denoted by $h_{ij}[X(t), \Theta, t]$, $i = 1, 2, \dots, n_1$; $j = 1, 2, \dots, n_2$. The problem of system reliability is written as

$$P_S = 1 - P_F = 1 - P \left[\bigcup_{i=1}^{n_1} \bigcap_{j=1}^{n_2} (h_{ij}^* - h_{ij}^M \leq 0) \right] \quad (19)$$

where $h_{ij}^M = \max_{t_0 \leq t \leq T} h_{ij}[X(t), \Theta, t]$. Here the structural system consists of n_1 , the number of subsystems connected in series, and each subsystem consists of n_2 , the number of components connected in parallel. A Monte Carlo estimator for the problem on hand is given as

$$\hat{P}_F = \frac{1}{N_1} \sum_{i=1}^{N_1} I \left[\bigcup_{i=1}^{n_1} \bigcap_{j=1}^{n_2} (h_{ij}^* - h_{ij}^M \leq 0) \right] \quad (20)$$

Studies on joint distributions of level crossing counting processes, first passage times, and extremes for vector of Gaussian random processes have been carried by Gupta and Manohar (2005) and Song and Der Kiureghian (2006). The study by Gupta and Manohar (2005) employs multivariate Poisson counting process model

and deduce joint distribution of extreme values as multivariate distributions with Gumbel marginals. These studies represent efforts to analytically model reliability specified with respect to more than one performance functions.

Existing Structures

Once an engineering system comes into existence, it becomes possible to measure its performance under operating and (or) ambient loads. In such cases, it becomes relevant to ask how the time variant reliability models can be updated based on observed performance of the system. Analysis of reliability of existing structures has been the subject of several studies in the existing literature (see, e.g., Melchers 1999).

The first natural step in the study of instrumented structures consists of identifying the parameters of the postulated mathematical model. Beyond the step of system identification, there exist several questions related to mathematical model updating such as reliability and local/global sensitivity model updating. The problem of system identification can be carried out within the framework of the dynamic state estimation methods (Ristic et al. 2004), and this can further be extended to problems of updating time variant reliability models of nonlinear dynamical systems (Ching and Beck 2007; Radhika and Manohar 2010; Sundar and Manohar 2013). In the study by Sundar and Manohar (2013), the performance functions considered are taken to be nonlinear functions of system states which are not necessarily measured. The analysis consists of two ingredients: the first that involves estimation of system states and performance metric conditioned on measurements and the second that involves estimation of reliability against future random excitations. The template for this framework consists of the following components:

1. Mathematical model for the structure, typically based on finite element analysis
2. A set of noisy measurements on structural displacements, strains, applied loads, and

(or) reaction transferred to the supports under operating and (or) diagnostic loads

3. A mathematical model which relates measured quantities to the system states in the governing mathematical model for structure. Both the models for structural behavior and the measurements are taken to be imperfect, and this is accounted for by including appropriate random noise terms in the models.

To illustrate this, consider the dynamical system governed by the discretized equation of the form

$$\begin{aligned} \mathbf{x}_{k+1} &= \boldsymbol{\phi}_k(\mathbf{x}_k, \boldsymbol{\theta}, \mathbf{f}_k, \mathbf{w}_k), \\ k &= 0, 1, \dots, N, \mathbf{x}_0 = \mathbf{x}(0) \end{aligned} \quad (21)$$

Here $\boldsymbol{\theta}$ is a $p \times 1$ vector of unknown system parameters, $\mathbf{x}_k$ and $\mathbf{f}_k$ are the $r \times 1$ state and externally applied force vectors in the time discretized form, $\boldsymbol{\phi}_k$ is a nonlinear state transition vector, and $\mathbf{w}_k$ is the $n_w \times 1$ process noise which represents the error in arriving at mathematical model for the vibrating system, modeled as a sequence of zero-mean Gaussian random variables with known covariance, i.e., $\langle \mathbf{w}_k \mathbf{w}_j^t \rangle = \mathbf{Q}_k \delta_{kj}$ where $\mathbf{Q}_k$ is $n_w \times n_w$, and δ_{kj} denotes the Kronecker delta function. Clearly the response vector, $\mathbf{x}_k$ would possess Markovian property.

The structure is assumed to be instrumented with s number of sensors which measure time histories of structural response, $\mathbf{Z}_k$, $k = 1, 2, \dots, N$. Let the measured response be related to the system states, $\mathbf{x}_k$, through the equation

$$\mathbf{Z}_k = \mathbf{H}_k(\mathbf{x}_k, \boldsymbol{\theta}, \mathbf{v}_k), \quad k = 1, 2, \dots, N \quad (22)$$

Here $\mathbf{Z}_k$ is an $s \times 1$ vector of measurements from the s sensors; $\mathbf{v}_k$ is the $n_v \times 1$ measurement noise term, modeled as a sequence of zero-mean Gaussian random variables with $\langle \mathbf{v}_k \mathbf{v}_j^t \rangle = \mathbf{R}_k \delta_{kj}$ where $\mathbf{R}_k$ is $n_v \times n_v$ covariance matrix; and $\mathbf{H}_k$ is a nonlinear function that relates the measurements to system states through a pertinent mathematical model. The measurement noise arises inherently

due to the sensor noise and also takes into account the error associated in the mathematical model used to relate the system states to the measurements made. It may be noted that $\mathbf{Z}_k$, $k = 1, 2, \dots, N$ could include measurements on applied forces, $\mathbf{f}_k$, as well. The notations $\mathbf{x}_{0:k} = \{\mathbf{x}_0, \mathbf{x}_1, \dots, \mathbf{x}_k\}$, $\mathbf{f}_{1:k} = \{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_k\}$, and $\mathbf{Z}_{1:k} = \{\mathbf{Z}_1, \mathbf{Z}_2, \dots, \mathbf{Z}_k\}$ will be used to represent the state, force, and response measurement matrices, respectively. For the sake of simplicity, the time step used in time discretization of governing equation and the sampling step used in obtaining measurements are taken to coincide.

Equation 22 represents the additional information that has been gained by making measurements on structural behavior. If attention is limited to Eq. 21 alone, as would be done at the design stage of the structure before it had come into existence, one can obtain response descriptions such as the multivariate joint PDF, $p_{\mathbf{x}_{0:k}}(\mathbf{x}_{0:k})$, and measures of structural safety based on suitably defined performance functions, $g(\boldsymbol{\theta}, \mathbf{x}_k)$. In such evaluations, one would employ models for the PDF of the system parameters, $p_{\boldsymbol{\theta}}(\boldsymbol{\theta})$, and the external excitation, $p_{\mathbf{f}_{1:k}}(\mathbf{f}_{1:k})$, based on analysis of available data and engineering judgment.

Once the structure is constructed and measurements become available, the problem of updating reliability models can be posed as the problem of determination of reliability of the structural system conditioned on $\mathbf{Z}_{1:k}$, i.e., $P_S|\mathbf{Z}_{1:k} = 1 - P_F|\mathbf{Z}_{1:k}$, where $P_F|\mathbf{Z}_{1:k}$ is the posterior probability of failure. In future discussions, for the sake of simplicity, subscripts in denoting PDFs are omitted. For instance, $p_{\mathbf{x}_{0:k}}(\mathbf{x}_{0:k}|\mathbf{Z}_{1:k})$ would be written simply as $p(\mathbf{x}_{0:k}|\mathbf{Z}_{1:k})$.

Dynamic State Estimation

Dynamic state estimation technique provides a logical framework for assimilating the measurement given in Eq. 22 into the mathematical model expressed as Eq. 21. It is assumed here that the quantities $p(\mathbf{x}_{k+1}|\mathbf{x}_k)$ and $p(\mathbf{Z}_{k+1}|\mathbf{x}_k)$ can be determined from the knowledge of $\mathbf{w}_k$ and $\mathbf{v}_k$. The problem of dynamic state estimation is stated as determining the multivariate posterior PDF $p(\mathbf{x}_{0:k}|\mathbf{Z}_{1:k})$ and its marginal PDF $p(\mathbf{x}_k|\mathbf{Z}_{1:k})$. The basic idea here is to propagate the PDF of the state vector, $p(\mathbf{x}_{k+1}|\mathbf{x}_k)$, from time step k to $k+1$ using the Markovian property of the vector $\mathbf{x}_k$ and Bayes' theorem to update the PDF of the states based on the available measurements. This can be expressed as a set of prediction and updating steps, given as follows:

$$\begin{aligned} \text{Prediction step : } p(\mathbf{x}_{k+1}|\mathbf{Z}_{1:k}) &= \int p(\mathbf{x}_{k+1}|\mathbf{x}_k)p(\mathbf{x}_k|\mathbf{Z}_{1:k})d\mathbf{x}_k \\ \text{Updating step : } p(\mathbf{x}_{k+1}|\mathbf{Z}_{1:k+1}) &= \frac{p(\mathbf{Z}_{k+1}|\mathbf{x}_{k+1})p(\mathbf{x}_{k+1}|\mathbf{Z}_{1:k})}{\int p(\mathbf{Z}_{k+1}|\mathbf{x}_{k+1})p(\mathbf{x}_{k+1}|\mathbf{Z}_{1:k})d\mathbf{x}_{k+1}}, \quad k = 0, 1, \dots, N \end{aligned} \quad (23)$$

Here $p(\mathbf{Z}_{k+1}|\mathbf{x}_{k+1})$ is called the likelihood function. The evolution of multidimensional

posterior PDF, $p(\mathbf{x}_{0:k+1}|\mathbf{Z}_{1:k+1})$, can be shown to be governed by the recursive relation

$$p(\mathbf{x}_{0:k+1}|\mathbf{Z}_{1:k+1}) = p(\mathbf{x}_{0:k}|\mathbf{Z}_{1:k}) \frac{p(\mathbf{Z}_{k+1}|\mathbf{x}_{k+1})p(\mathbf{x}_{k+1}|\mathbf{x}_k)}{p(\mathbf{Z}_{k+1}|\mathbf{Z}_{1:k})}, \quad k = 0, 1, \dots, N \quad (24)$$

For linear state-space models with Gaussian additive noise, the state estimation problem can be tackled exactly using Kalman filter, while for

more general class of nonlinear, non-Gaussian systems, particle filtering methods are employed. The second step involving reliability prediction

for both these classes of problems typically requires the application of Monte Carlo strategies.

Updating Reliability Models

Equations for the evolution of the updated PDF (i.e., after assimilating the measurements) similar to the ones given in section “[Markov Vector Methods](#)” can be derived. These are called the Kushner–Stratonovich equations. For most practical problems of interest, with nonlinear process and measurement equations, non-Gaussian noises, this equation remains theoretical in nature and suffers from the moment closure problem (Maybeck 1982). Thus updating reliability models is mostly carried out through the simulation-based methods.

The Kalman filter-based dynamic state estimation tools in combination with Monte Carlo simulation methods can be employed to estimate probability of failure in instrumented structures with performance functions encompassing unmeasured system states (Ching and Beck 2007). The variance reduction strategies developed in the context of reliability analysis when applied in conjunction with the dynamic state estimation techniques could be used to determine the updated probability of failure of the structural system. For example, the data-based extreme value analysis and the Girsanov transformation-based method can be used to determine the reliability of existing structures (Radhika and Manohar 2010; Sundar and Manohar 2013).

Summary

The problem of time variant reliability analysis of nonlinear dynamical systems can be studied to a limited extent through analytical methods and more comprehensively with simulation-based strategies. The analytical approximations are based on theory of outcrossing statistics and Markov vector approaches. Monte Carlo simulation-based methods invariably need to be reinforced with suitable variance reduction strategies so that the resulting tools become applicable to tackle

realistic problems. These tools are versatile to handle various complexities associated with treatment of structural nonlinearities, mutually dependent non-Gaussian random variables, spatially varying random fields, non-stationary random vector excitations, and estimation of probability of rare events. When structure comes into existence and its responses are measured, the analysis of reliability can be carried out by combining Bayesian updating/filtering tools with simulation-based strategies to assess structural reliability against future loads. This entry provides a snapshot of current state of art in this subject.

Introduction

The reliable determination of earthquakes source moment tensor and of its uncertainty is of key importance for both geodynamic investigation and seismic hazard assessment.

The knowledge of the focal mechanism (i.e., fault plane solution) in fact provides essential indications about the kind of rupture process affecting the fault and thus, besides the event's strength (i.e., seismic moment and magnitude), gives a first-order description of the local stress field acting on the fault. This information can be used not only to constrain geodynamic

interpretations relying on seismological and geophysical data modeling but also as an input in deterministic seismic hazard analysis (DSHA or NDSHA, Panza et al. 2012), providing the depth of the fault and its style of dominant displacement. The information provided by moment tensor inversion may enter as an input even in the probabilistic seismic hazard analysis (PSHA), providing fault geometry and dislocation mechanism that critically affect ground motion prediction equations (GMPEs), and, if incorrectly determined, may lead to unreliable results.

Many different methods use intermediate- to long-period waveforms, from regional to global distances, and are routinely applied to obtain “real-time” focal mechanism determinations for moderate to strong earthquakes. The routinely applied centroid moment tensor (CMT, Dziewonski et al. 1981) is one of the most popular methodologies for the determination of moderate to strong ($M > 5.5$) event’s focal mechanism, even if it has been proven that supplied focal depths can be severely in error (Chu et al. 2009). This method uses filtered body waves at period >45 s for moderate events and mantle waves filtered at period >135 s for stronger ones. CMT is not useful to determine focal mechanisms of low to moderate magnitude events, which are not resolved by teleseismic waves. Thus, in the last decades, inversion methods were extended to the use of regional to local seismograms and routinely used wherever the presence of a broadband seismic network is available. The regional centroid moment tensor (RCMT, Arvidsson and Ekström 1998), for example, provides focal mechanism determinations for events of $M > 4.5$ in the Euro-Mediterranean region, using regional surface wave records filtered at period >35 s (60 s for strongest events). RCMT is routinely used since 1997, i.e., since the broadband network coverage allows the use of the quite high number of stations needed by the inversion method. In fact a reanalysis by means of RCMT method (Pondrelli et al. 2006) of events that occurred in the period 1977–1997 in the Italian region shows that a low number of recording stations as well as their sparse azimuthal distribution badly constrains the inversion results.

Both CMT and RCMT methods suffer the instability of two elements of the moment tensor (namely, M_{zx} and M_{zy}) that are poorly resolved when waves whose wavelength significantly exceeds the hypocentral depth are used (Bukchin et al. 2010). To overcome this problem, with CMT and RCMT, usually the depth of shallow events is fixed during the inversion, either at 10 or 15 km of depth. Instability also affects moment tensor determination itself and gives rise to spurious large compensated linear vector dipole (CLVD) components and, in some cases, to pairs of best double-couple (DC) solutions equally well fitting the recorded waveforms (Henry et al. 2002).

In the following, the INPAR nonlinear inversion method (Šílený et al. 1992) is described that is suitable for the retrieval of earthquakes moment tensor and of its uncertainty for small to moderate earthquakes ($1.5 < M_w < 6.0$). INPAR that can handle periods as short as 0.2 s has been successfully applied in tectonic as well as in geothermal and volcanic environment, where it proved its capability to retrieve reliable non-DC components (e.g., Saraò et al. 2010).

With respect to the most inversion methods, INPAR (a) requires the use of a very limited number of full waveforms at the shortest wavelengths compatible with the source dimension and epicentral distance and (b) has the capacity to absorb, at least partially, spurious effects due to the epistemic uncertainty of the models describing the geological structure where the source is buried. On account of properties (a) and (b), the availability of average models and of a few well-recorded signals is sufficient for its application as shown here, for example, in Italy, Vrancea, Antarctica, and Egypt.

The instability of M_{zx} and M_{zy} can be successfully mitigated by the use of short-period waveforms and, therefore, largely improves the reliability of the moment tensor determination of shallow events. In addition, the flexibility of the method allows sorting out a spurious CLVD component from that arising from a mechanism changing in time and gives deeper insight in the rupture process of complex events.

Methodology

The INPAR method for the inversion of moment tensor adopts a point-source approximation. The retrieval of the six components of the moment tensor by waveform inversion is a nonlinear problem; anyway linearity can be preserved in the first step of the inversion by considering different time evolutions for each of the six components of the moment tensor, namely, the moment tensor rate functions (MTRFs, Panza and Saraò 2000). The k_{th} component of displacement at the surface is the convolution product of the MTRFs and (medium) Green's function spatial derivatives (hereafter Green's functions) and, using Einstein summation notation, can be written as

$$u_k(t) = \dot{M}_{ij}(t) * G_{ki,j}(t) \quad (1)$$

The moment rate functions are obtained by deconvolution of Green's functions from the data. The synthetic Green's functions are computed using the modal-summation technique (Florsch et al. 1991) at each grid point of a preassigned volume around estimated hypocentral coordinates and, by linear interpolation, in the intermediate points of this volume according to an a priori defined step. Thus, INPAR performs if necessary a dynamic relocation of the hypocenter, which is crucial, since its bad location may strongly affect the result of the inversion. The hypocentral location is searched until the difference (in terms of L_2 -norm) between synthetic and observed seismograms is minimized with respect to a preassigned threshold.

Considering each MTRF as independent functions in the first step of inversion leads to an over-parameterization of the problem which is advantageous for absorbing poor modeling of the structure (epistemic uncertainty, Kravanja et al. 1999).

In the second step, the source mechanism and time function are obtained after factorization of the MTRFs into a time constant moment tensor m_{ij} and a common source time function $f(t)$:

$$\dot{M}_{ij}(t) = m_{ij} \cdot f(t) \quad (2)$$

This means that the same time dependence for all moment tensor components, i.e., a rupture mechanism constant in time, is assumed, which is an acceptable approximation for weak to moderate earthquakes. Only the correlated part of the MTRFs is used in the factorization, thus absorbing the bias due to non-exact Green's functions (Panza and Saraò 2000); the problem is nonlinear and is solved iteratively by imposing constraints such as positivity of the source time function and the requirement of a mechanism consistent with clear readings of at least one first-arrival polarity.

The final solution and related uncertainties are obtained by means of a genetic algorithm (Šílený 1998) which finds out the point where the misfit function is a minimum and at the same time maps the model space in its vicinity with the aim of estimating the confidence regions of the model parameters.

In summary, the average mechanism and source time function obtained by the inversion are considered to be basically affected by three kinds of bias, generated, respectively, by: (1) the noise present in the data. (2) the horizontal mislocation of the hypocenter, and (3) the epistemic uncertainty in the structural models used to compute the synthetic Green's functions.

Examples of Applications and Discussion

Application to Tectonic Events

The INPAR method has been applied for the retrieval of the moment tensor of tectonic events in different regions of the Earth, especially where the geographic features and logistic determine an uneven distribution of seismic stations (like in Italy, Antarctica, and Egypt).

In Italy INPAR has been routinely applied to determine the focal mechanisms of major, potentially damaging earthquakes ($M_w \geq 4.8$) since 1997. The comparison with the solution obtained using longer periods of data, performed by different authors (Guidarelli and Panza 2006; Brandmayr et al. 2013), points out differences in the hypocentral depth, especially in those cases in which depth is a priori fixed by CMT and RCMT.

Reliable Moment Tensor Inversion for Regional- to Local-Distance Earthquakes,

Fig. 1 Fault plane solution of the major events ($M_w \geq 4.8$) that affected Italy since 1997, determined by INPAR method. Different colors represent different source depth intervals

In some cases the relocation in depth is accompanied to a different fault plane solution, as a consequence of the improved resolvability of the M_{zx} and M_{zy} moment tensor components, allowed by the use in INPAR of much shorter periods than in CMT and RCMT.

The synoptic view of all the events inverted by INPAR method (Fig. 1) is relevant for the understanding of the ongoing geodynamic process in the Italian region.

Most of the events occurred in central Apennines: two major seismic sequences hit Umbria and Marche regions (in 1997) and the city of L'Aquila (in 2009). Most of the hypocenters in this area are located in the crust (≤ 35 km of depth) and the prevalent fault mechanism is normal, in accordance with the ongoing extensional tectonics. Besides normal faulting, a relevant number of strike-slip events are present, likely representing zones of accommodation

of different extensional stress rates through the Apennines chain.

A more complex seismic pattern characterizes the northern part of the Apennines and the related Po Plain foredeep, where a major seismic sequence hit in 2012 (Brandmayr et al. 2013). Normal faulting prevails in the inner front, as shown by Pondrelli et al. (2006) in their review of the CMT and RCMT Italian dataset. Conversely, thrust to strike-slip faulting is dominant in the external front and on the buried faults below the Po Plain. Some lower crust earthquakes show a clear strike-slip mechanism, probably generated by buried faults located at the salient-recess interfaces.

Relevant intermediate (36–100 km) seismicity is present in the northernmost part of the Apennines, both on the inner and the external front. Northeastern Alps shows limited seismicity in the considered magnitude and time range, and the

Reliable Moment Tensor Inversion for Regional- to Local-Distance Earthquakes, Fig. 2 Focal mechanisms associated to the seismogenic nodes (circles) in the Po Valley from different sources: mean focal mechanism of seismogenic zone (Meletti and Valensise 2004) that contains the center of the node (blue), mean focal mechanism of events of EMMA database (Vannucci and

Gasparini 2004) that falls inside the node (green), focal mechanism of fault contained in Database of Individual Seismogenic Sources (DISS Working Group 2010) associated to the node (red). The reliability of the focal mechanism determination is crucial to define the average mechanism associated to each node and thus for realistic computation of hazard scenarios

observed shallow thrust to strike-slip mechanisms is fairly in agreement with the compressional tectonics of the area.

In southern Italy, major seismic activity is mostly concentrated along the Calabrian arc and the Tyrrhenian margin, with few events in the Ustica volcanic area. The only deep events (>100 km) in the Italian region are located in the inner front of the Calabrian arc, where the seismicity extends till 350 km of depth.

The reliable determination of the focal mechanisms also represents a key input for PSHA and NDSHA, to the latter in particular for the definition of the seismogenic nodes (Fig. 2).

Seismogenic nodes are earthquake-prone areas identified through morphostructural analysis (e.g., Gorshkov et al. 2002), and, in the framework of NDSHA, possible seismic sources are associated with them (Panza et al. 2012). Reliable focal mechanisms associated to nodes are crucial to compute the seismic hazard scenarios. Nevertheless, if a seismogenic node presents different associated mechanisms, parametric tests used in the NDSHA allow to compute different scenarios, in between which the worst can be taken as representative. Conversely, the way in which information about focal mechanism eventually enters in PSHA (i.e., as an average of different

mechanisms in the GMPE) badly affects the prediction scenario in case of unreliable moment tensor determinations.

Application of INPAR to tectonic events in Antarctica represents a suitable procedure in an environment such as the Scotia Sea region, where (1) the high level of seismic noise, typical of the oceanic environment, hampers the use of standard inversion techniques based on first-arrival polarities, (2) a low number of operating stations are present due to logistic, (3) the structural models are grossly known, and (4) the epistemic uncertainty is thus considerable.

Vuan et al. (2001) performed some feasibility tests, with particular attention to the distribution of the recording stations (i.e., their azimuthal coverage with respect to the source) for a synthetic event located at the South Sandwich Trench. The results show that a great improvement of the quality of the solution could be gained with the addition of only one ocean-bottom seismometer to the set of permanent seismic station deployed in 1997. The subsequent inversion of two real events, located by INPAR at depth of 90 and 15, respectively, is substantially in agreement with the results obtained by CMT. Guidarelli and Panza (2006) retrieved the moment tensor solutions of six events occurred in Bransfield Strait between 1997 and 1998, and Plasencia (2006) analyzed the seven major aftershocks of the Centenary Earthquake (2003/08/04, 04:37:19 GMT, 7.6 M_w), located along South Scotia Ridge.

The source mechanisms obtained are quite variable but consistent with the active tectonic processes and the complicated structure of the South Shetland Island region. The mechanisms around Elephant Island reflect the influence of the Elephant triple junction, with the intersection of the Shackleton Fracture Zone, the South Shetland Trench, and the South Scotia Ridge. In the forearc, north to the South Shetland Islands, the solutions obtained by Guidarelli and Panza (2006) seem to confirm the presence of active convergence along the South Shetland subduction zone, while Plasencia (2006) evidences the presence of both transpressive and transtensive

areas along the northern border of the South Orkney Microcontinent.

The inversion of local waveforms at high frequency (up to 5 Hz) by means of INPAR method has been applied both for shallow and deep weak to moderate tectonic events in Vrancea region and in eastern Carpathian bending zone (e.g., Ardeleanu et al. 2005).

The power of INPAR with respect to the traditional methods based on the inversion of polarities or amplitudes is obvious in the case of small earthquakes when few records are available and/or the noise distorts significantly or masks the first arrivals.

In these cases, the reliability of the solutions has been determined through a bootstrap-like procedure, consisting in inverting subsets of the available data combined with the rejection of obvious outliers, i.e., solutions that deviate strongly from the average. This procedure allowed limiting the distortion of source parameter due to the large epistemic uncertainty in the structural model of the region.

The estimated uncertainty of the resolved fault plane solutions for both shallow and intermediate depth events allowed reliable correlations with the stress field in the study area. The new data provided about the complex picture of the deformation field in the crustal and subcrustal domain of the Vrancea seismogenic region (a) indicate the transition from the compressive regime at intermediate depth to the extensional regime in the crust, characteristic over the Moesian platform, (b) point out the occurrence of events whose mechanism strongly deviates from the average mechanism of the area, and (c) show a large variability which could be caused by coseismic and postseismic relaxation associated with the Vrancea events generated in the subcrustal region.

Recently INPAR has been applied to a swarm of 15 small events ($1.7 < M < 3.7$) which occurred in August 2004 in the Abu Dabbab area (Egypt). The absence of a large seismic main shock, the periodically recorded swarms in the area, and the retrieved tensile earthquakes with a relatively high CLVD component are

considered evidence supporting igneous activity-related events (Ali et al. 2012).

Application to Volcanic and Geothermal Events

When dealing with seismic events in volcanic and geothermal environment, it is necessary to investigate full moment tensor, i.e., double-couple component (DC), compensated linear vector dipole component (CLVD), and isotropic component (V). In fact non-DC mechanisms in volcanic and geothermal environment can be indicators of local modifications of the stress fields induced by dikes injections as well as thermal cooling or high fluid pressure. It is thus crucial to sort out reliable non-DC components from the artificial ones that can arise from poor modeling of the structure, noise level, or inhomogeneous azimuthal station's coverage.

Panza and Saraò (2000) performed a systematic review of the possible sources of false non-DC components on low-magnitude events in volcanic and geothermal environment. They analyzed in particular events from Phlegraean Fields and Mt. Vesuvius, Larderello geothermal field (Tuscany), and Mt. Etna; spurious non-DC components can be identified with a confidence level between 95 % and 99 % through an appropriate error analysis like the one allowed by the use of a genetic algorithm (Šílený 1998), especially if the temporary evolution of the non-DC component is investigated as well. Reliable assessment of non-DC components in geothermal and volcanic environment is crucial for the geodynamic modeling of the magma or fluid sources, as shown by Saraò et al. (2010) who described, in the 2001 Mt Etna's eruption seismic swarm, an increase with increasing time of the non-DC component that is compatible with a complex stress regime naturally generated by vertical dike's propagation.

Summary

The reliable determination of earthquakes' moment tensor and of its uncertainty is of key importance for both geodynamic investigation

and seismic hazard assessment. Many different methods use intermediate to long period waveforms, from regional to global distances, and are routinely applied to obtain "real-time" focal mechanism determinations for moderate to strong earthquakes. A nonlinear inversion method is described that is suitable for the retrieval of earthquakes' moment tensor and of its uncertainty of small to moderate earthquakes ($1.5 < M_w < 6.0$), both in tectonic and volcanic environment, and that needs the use of a very limited number of full waveforms at the shortest compatible periods with the source dimension and epicentral distances.

The well-known instability of two elements of the moment tensor (M_{zx} and M_{zy}), which can give rise to very large spurious compensated linear vector dipole (CLVD) components and equally well-fitting pairs of solutions, is successfully mitigated by the use of short-period waveforms and, therefore, largely improves the reliability of the moment tensor determination of shallow events, which are affected by this instability when the relevant wavelength of the inverted signals significantly exceeds the source depth. In addition, the flexibility of the method allows to discriminate a spurious CLVD component from that arising from a mechanism changing in time and gives a deeper insight in the rupture process of complex events.

This method has been widely applied in different regions, whose seismic stations' spatial distribution often requires the use of few records like Italy, Vrancea, Antarctica, and Egypt, and some outstanding examples are given.

Introduction

This entry is focused on the use of remote sensing in seismology for coseismic deformation detection, measurement, and modeling. Today the Earth sciences have a wide range of instruments and sensors that can provide scientists with a novel capability to study the physical processes driving earthquakes, volcanic eruptions, landslides, land subsidence, etc. In particular since the last 20 years, satellite missions devoted to Earth observation aims have been increased in number and improved in performances. Satellites allow systematic observation over large areas, over a long time period, and with frequent sampling. Such properties make satellites suitable to be used for studying the surface effects of earthquakes, which can be summarized in the effects on buildings and manufactures, and surface displacements.

This overview cannot be exhaustive of all the domains where remote sensing is applied in seismology. Indeed it is focused on the use of a specific techniques applied on satellite microwave data, named synthetic aperture radar (SAR), and on the application of a SAR processing technique known as InSAR (interferometric SAR) and its variation DInSAR (differential InSAR). It is worth noting how a comprehensive review about the use of remote sensing to cover the whole area of seismological studies would request to go deeper in details about more complex approaches for processing. The scope of the overview is simply to provide useful hints and references to who is interested to more specific studies.

In this overview concerning the use of remote sensing for seismological applications, some topics are beyond the aim of the entry, so as the technical details of InSAR and the use of optical satellite images for damage assessment, being the purpose of further contributions and will be debated elsewhere in the “Remote Sensing” section of the encyclopedia.

Satellite DInSAR

Among satellite sensors synthetic aperture radar has played a key role in the geosciences. The first

ever civilian SAR systems is the NASA Seasat (1978) satellite, the first satellite designed for remote sensing of the Earth’s oceans with a SAR sensor and used L-band (24-cm wavelength) radar. The aim of Seasat was to demonstrate the feasibility of global satellite monitoring of oceanographic phenomena and to help determine the requirements for an operational ocean remote sensing satellite system. Seasat was also used to provide the first demonstration of DInSAR to detect surface motion due to soil swelling (Fig. 1) in the Imperial Valley, California (Gabriel et al. 1989). The authors simply but efficiently summarize the essential properties of DInSAR, affirming: “can measure accurately extremely small changes in terrain over the large swaths associated with SAR imaging, especially since the sensor can work at night and through clouds or precipitations.”

Seasat was followed in 1991 by ERS-1 satellite launched by the European Space Agency (ESA), with a C-band (5.6-cm wavelength) SAR system, which was joined by ERS-2 a few years later (1995). In parallel, the National Space Development Agency of Japan (NASDA, now JAXA- Japan Aerospace Exploration Agency) developed an L-band SAR sensor that was launched into orbit onboard the JERS-1 satellite, in 1992. In 1995 the Canadian Space Agency (CSA) launched RADARSAT-1, an advanced Earth observation satellite (<http://www.asc-csa.gc.ca/eng/satellites/radarsat1/default.asp>), to monitor environmental change and to support resource sustainability. In 2002, ESA launched Envisat, an advanced polar-orbiting Earth observation satellite, which, among other instruments, operated an Advanced SAR (ASAR) system, a partially polarimetric instrument (capable of measuring different polarizations of the radar signal) with seven imaging swaths (I1–I7 modes), each with a different incidence angle, along with a wide-swath mode capable of producing 250-km-wide SAR images. In January 2006, JAXA launched the ALOS (Advanced Land Observing Satellite). ALOS carried optical instruments – PRISM and AVNIR – and the Phased-Array L-band Synthetic Aperture Radar (PALSAR). Starting in 2007, a new generation of

Remote Sensing in Seismology:

An Overview, Fig. 1 First demonstration of differential InSAR using Seasat data to detect vertical motions over a few days caused by soil swelling of irrigated fields in the Imperial Valley, California (From Gabriel et al. 1989). Differential interferogram (*top*) of the Imperial Valley and (*bottom*) double difference interferogram obtained by combining two interferograms as showed in the *top*. *Black areas* correspond to coherence loss

Plate 1a. Single-difference interferogram of Imperial Valley. Phases are presented as color and are shown. The fields with noisy phases had apparently been plowed between observations, resulting in a loss of phase coherence.

Plate 2. Double-difference interferogram of the Imperial Valley. Two interferograms like Plate 1 were differenced to generate this image, which shows changes that occurred between the observations. The dominant yellow color represents zero phase change, as evidenced by the very bright yellow spot on the left center, which is a radio tower. Black areas represent the loss of phase coherence, where the noisy phases of Plate 1 have been left out. The various colors, from blue to red to green, indicate small motions (2-3 cm) of the fields from swelling or shrinkage associated with watering.

high-resolution SAR systems was launched that revolutionized the panorama of available instruments. The German Aerospace Agency (DLR) launched TerraSAR-X, an X-Band system able

to operate in four modes (from High-Resolution Spotlight, 1-m resolution, to ScanSAR, 18 m). The Italian Space Agency (ASI) launched its first high-resolution X-Band SAR satellite,

COSMO-SkyMed-1, in 2007. COSMO-SkyMed's capabilities include very high resolution (up to 1 m), polarimetric modes and right-left lateral view options. With its RADARSAT-2 program, the CSA provides data continuity for RADARSAT-1 users. RADARSAT-2 has new capabilities including the high-resolution (3-m) Ultra Fine mode, full polarimetric capabilities, and right-left looking view.

It has been more than 20 years since the first successful applications of InSAR to measure large-scale surface deformation, characterizing the coseismic displacement field of the Landers earthquake (Massonnet et al. 1993). InSAR is a SAR data processing technique aimed at estimating any variation of the phase component of two or more SAR images acquired along the nominally same orbit (Rosen et al. 2000). The phase is related to the satellite-to-target distance, which is composed of a large number of integer wavelengths and the measured fractional phase component. The result of the application of InSAR is the so-called interferogram, that is, the pixel-to-pixel difference of the phase components of two SAR images covering the same area. Differential InSAR (DInSAR) is the technique applied to generate topographically corrected interferograms, where the topographic phase contribution measured in the interferogram is removed using a digital elevation model (DEM) (Rosen et al. 2000). The result of DInSAR application is an interferogram containing the displacement vectors along the satellite line of sight (LOS). This means that DInSAR measures the result of the projection of the North, East, and Up components of three-dimensional surface displacements into the LOS. In order to obtain a LOS displacement map, a "phase unwrapping" algorithm is applied to the result of DInSAR (Fornaro et al. 1996).

Coseismic Displacements

The capability of DInSAR to detect centimetric movements over large areas has been successfully used in seismology, where traditionally the main topic of scientists is to determine the source parameters (the fault parameters). An earthquake occurs

along a fault plane, that is, a discontinuity in the crust, when the stress applied exceeds a certain threshold. The size of an earthquake is measured by the seismic moment, while the moment magnitude (M_w) is the energy released (Kanamori 1977). M_w is measured over a scale of 10^0 (0–10, real numbers). From scientists' experience it is commonly shareable that surface deformation occurs in case of M_w over 5.0 and shallow hypocentral depth (up to 5 km). In recent years some reviews have been focused on defining such thresholds (Dawson and Tregoning 2007) and the trade-off magnitude-depth. DInSAR provides high spatial resolution of surface deformation and is able to provide reliable constraints to the fault location, to geometric parameters (depth, fault dimension, strike, dip), and to the definition of the average slip. DInSAR is also capable to provide an estimate of the geodetic moment, which now rarely differs from the seismic moment (Feigl 2002). Indeed the geodetic moment is the result of the estimation of released slip so as it derives from the surface displacements detected from DInSAR. Such displacement is the result of the coseismic deformation, plus secondary (but not negligible) contributions from post-seismic and aseismic deformations.

It is not far from truth saying that DInSAR has become a key tool in the Earth Sciences domain. Today it is a reliable input to modeling tools, either for simple or complex methods. Many models deals with the Okada formulation (Okada 1985) that implies the use of a uniform elastic half space. Improved data constraints and use of sophisticated modeling and inverse methods allow exploring variation of elastic properties in layers or more complex representation of faults and rheology (Masterlark and Hughes 2008). In recent years, DInSAR measurements combined with traditional seismological data have also been used for rupture models including constraints on rupture propagation and velocity (Fielding et al. 2013).

Case Studies

In the following sections, some examples of applications of DInSAR are showed. The aim is

to give the reader useful hints about the capabilities of DInSAR technique to measure earthquake-induced deformation. Today the earthquakes studied with the key contribution of DInSAR are more than 100. The case studies focused in the following are, for various reasons, among the most well known worldwide. Indeed among them is the first ever seismological application of DInSAR, the first ever in Europe to a seismic sequence with three mainshocks, one of the largest earthquakes in seismological instrumental history, etc.

Landers (1992)

The Mw (moment magnitude) 7.3 Landers earthquake of June 28, 1992, that ruptured over 85 km along a fault system is the first case study where DInSAR has been successfully applied to the measurement of the surface displacement field and allowed to provide a detailed image of the overall deformation field. Field observations and seismological data have shown right lateral slip up to 4 m and 6 m at about 10 km and 40 km north of the mainshock, for which the hypocentral depth is between 3 and 8 km. It is worth noting that the Landers earthquake was followed 3 h later by a Mw 6.2 (called the Big Bear) that, notwithstanding the magnitude, did not provoke any surface displacement. Coseismic “geodetic” displacements have been measured by GPS (Global Positioning System) (up to 3-m horizontal offset) (Hudnut et al. 1994) and pixel correlation from SPOT satellite (1-m displacement) (Michel and Avouac 2006). However the absolute novelty has been the analysis performed using a pair of SAR ERS-1 images (April 24–August 7, 1992). The result (Fig. 2) revealed a complex deformation surrounding a series of discontinuous strike-slip rupture segments in the Mojave Desert that stretched over about 70-km length. The maximum relative change in distance between the satellite and the ground (line of sight) produced by the earthquake was about 1 m across the fault, caused by around 6 m of slip on the fault. Deeper in detail the coseismic interferogram reveals no organized fringes in a band within 5–10 km of the fault trace, probably due to the high displacement gradient recorded in

Remote Sensing in Seismology: An Overview, Fig. 2 Coseismic interferogram for the Landers earthquake (From Massonnet et al. 1993). A color cycle represents a chance distance of 28 mm along the satellite LOS. *Black segments* depict the fault geometry as mapped in the field

this area exceeding a critical value detectable by DInSAR. Or, additionally, crustal block rotation may have reduced the coherence. A theoretical model based on Okada formulation has been performed by applying to each rectangular patch 2 km long a constant slip taken from the offset mapped on the field. The model extends from 0- up to 15-km depth, in order to match the seismic moment. It is interesting to see where the measured fringe pattern and the model differ. The main discrepancies are local complexities or short-wavelength features near the fault rupture, whereas the local concentration of strain is highly sensitive to the detailed geometry of the fault.

Umbria-Marche (1997)

In September 1997 a large area of Umbria-Marche Apennines (Central Italy) was struck by a strong seismic sequence. A foreshock occurred on September 3 (Mw 4.5), while two mainshocks took place on September 26 (00:33 GMT, Mw 5.7; 09:40 GMT, Mw 6.0). Some days later, on October 14 a Mw 5.6 occurred toward South, around the village of Sellano. This is one of the

Remote Sensing in Seismology:

An Overview,

Fig. 3 Coseismic interferogram of the Umbria-Marche earthquake in September 1997. Fringes (black-white contours) correspond each to a LOS displacement of 28 mm. The two mainshocks are indicated by the source mechanisms (black-white beach balls), hour (GMT), and dates (From Stramondo et al. 1999)

earliest applications of DInSAR in seismology worldwide, the first in Europe (the second since ever after Grevena, 1995, Greece) concerning a complex sequence characterized by multiple mainshocks and thousands of minor events. Indeed 1,650 earthquakes with magnitude between 2.5 and 6 have been recorded in a period of 40 days in the area (Chiaraluce et al. 2003). This moderate-magnitude earthquake sequence caused a broad damage pattern and extensive concern among the population in the region. Due to the shallow depth of these earthquakes (less than 8 km), the ground shaking at the surface has been very large. The 1997 Umbria-Marche earthquake sequence in the

complex tectonic setting of the North Apennine offers the possibility to unravel the anatomy of a normal fault system and to investigate fault segmentation. The map of coseismic deformation has been obtained by a pair of ERS-2 images (September 7–October 12), so that it contains the surface movements due to both September 26 events. The interferogram (Fig. 3) shows some fringes (gray contours) that trace a bean-shaped pattern NW-SE oriented with a maximum LOS displacement of about 25 cm close to Annifo village. At the same time, one of the four GPS benchmarks in the epicentral area measured about 14-cm horizontal and about 24-cm vertical movements. Either GPS or DInSAR has been the

Remote Sensing in Seismology: An Overview, Fig. 4 Synthetic coseismic interferogram of the Umbria-Marche earthquake in September 1997. The fault plane has been divided in 15 patches at different

depths. Synthetic fringes (*black-white contours*) correspond each to a LOS displacement of 28 mm. Measured (*in red*) and modeled (*in blue*) GPS horizontal vectors are also shown (From Stramondo et al. 1999)

input data to an inversion modeling program that has provided an estimation of the fault parameters (Stramondo et al. 1999) and the distribution of the slip over the fault plane (Fig. 4).

The geophysicists and seismologists have benefitted from the additional information from DInSAR that has provided a picture of the overall displacements projected onto the LOS. Indeed differently from the results of ground surveys that give a sparse spatial sampling of the deformation field, DInSAR makes available to scientists a spatially continuous view of such field.

Bam (2003)

On December 26, 2003, southeastern Iran was shaken by a destructive earthquake (Mw 6.5). The event was located near the city of Bam and the Bavarat village (Fig. 5) and nucleated at

a depth below 10 km. Seismic focal mechanism suggests that slip occurred along a high-angle dipping fault plane, with a prevailing strike-slip sense of motion.

Before this earthquake occurred, the “Bam fault” was the major tectonic feature mapped in the epicentral area (Fig. 5), extending along the west side of Bavarat village (i.e., Fu et al. 2004). Initially, the December 2003 shock has been associated to this fault. Although the reports on field investigations describe the surface features produced by the event such as landslides, liquefactions, sinkholes, and fractures particularly concentrated between the city of Bam and Bavarat village (Zaré 2003), none of these surface features have been interpreted as evidences for surface dislocation directly associated to the Bam fault. In other words, such secondary effects

Remote Sensing in Seismology:

An Overview,

Fig. 5 Landsat 7 Enhanced Thematic Mapper Plus (ETM+) image of the Bam earthquake area (<http://www.parstimes.com/spaceimages/bam/landsat.html>). Red line is the fault inferred from InSAR data; this fault has been recognized as the earthquake source. Dotted black line is the Bam fault. The star indicates the epicenter location; focal mechanism (beach ball) is from USGS website (Modified from Stramondo et al. 2005)

are not located around the fault responsible for the earthquake. In this case, DInSAR outcomes heavily contributed to infer location and geometry of the unknown fault that is the source of the earthquake. It is noteworthy how the hypocenter distribution of aftershocks recorded by a temporary seismic network installed some weeks after the seism is in good agreement with geometric parameters derived from DInSAR.

A dataset of Envisat ASAR data acquired from two different geometries (ascending and descending orbits) has been used for DInSAR analyses. In particular, about 4 km west of the Bam fault (black dashed line in Fig. 5), the fringes of displacement reach the maximum gradient (Fig. 6) along an averaging north–south direction suggesting location, length, and azimuth of the fault (red line in Fig. 5) (Stramondo et al. 2005a). The fault, named Arg-e-Bam, is almost 20 km long, and the northernmost portion (about 5 km) is exactly beneath the city of Bam.

The combination of the satellite LOS with the mechanism of the fault results in a positive

displacement (satellite-to-surface distance increase) measured in the descending interferogram of ~ 25 cm occurring within the southern lobe. Conversely, the lobe to the north has a maximum LOS movement equal to about -24.5 cm. This different sense of motion along the same fault side may be explained by the very low angle between the fault strike (fault alignment) and the satellite orbital direction and due to strike variations along the fault (see Fig. 7). The map of displacements has been used to simulate the distribution of slip over a fault plane, starting from the fault parameters constrained by DInSAR and seismological data. The synthetic interferogram obtained by an 18×12 km fault plane (see Stramondo et al. 2005b) fits well with the descending interferogram. The proposed model is a very simple representation of the reality, meaning that local complexities in the slip distribution and fault geometry have not been included (see Fig. 8). The aim, in the Bam case study and more generally in seismology, is first to provide a fast and draft view of the seismic

Remote Sensing in Seismology: An Overview, Fig. 6 (left) Coseismic interferogram from descending Envisat orbit (December 3, 2003–January 7, 2004); (right) coseismic interferogram from ascending Envisat orbit

(January 25, 2004–November 16, 2003). The *red lines* in both figures indicate the satellite LOS. Each color cycle corresponds to ~ 2.8 -cm displacement (From Stramondo et al. 2005)

source. Later, if necessary and where available data allow it, deeper and more complex analyses can be performed.

L'Aquila (2009)

On April 6, 2009 (01:32GMT), a large portion of Abruzzi region and in particular the city of L'Aquila (Central Italy) were hit by a seismic sequence whose main event (M_w 6.3) occurred very close to the historical center (Walters et al. 2009). In L'Aquila and in the neighboring villages, the earthquake caused collapse or irreparable damage to over 15,000 buildings, killing 308 people and causing the relocation of over 65,000. The mainshock was followed by seven major aftershocks ($M_w > 5$), and over 6,000 smaller events occurred in the next few months in an area extended northwest–southeast for about 35 km.

L'Aquila 2009 is the first ever case study where X-, C-, and L-band SAR data have been available for the same earthquake (Stramondo et al. 2011b). SAR data coming from COSMO-SkyMed, Envisat, and ALOS satellites, allowed an unprecedented coverage of a coseismic displacement field in terms of different line of sights (LOS), ground resolutions, and frequency bands of the imaging sensors (Fig. 9). Notwithstanding this, in the early post-earthquake, attempts to determine the location of the seismic source were hampered by the lack of clear surface faulting. Indeed only 6 days after the seism, the first meaningful interferograms were obtained by COSMO-SkyMed and Envisat (descending orbit).

The COSMO-SkyMed interferogram shows a northwest–southeast concentric fringe pattern composed of 12 fringes, each corresponding to

Remote Sensing in Seismology: An Overview, Fig. 7 Planimetric and along-orbit (azimuth) oriented sketch of Envisat geometries along ascending and descending paths. Planimetric view (*top*) shows horizontal displacement vector and their projection in planimetry along each LOS (*in blue*); azimuth view (*bottom*) provides LOS projection of ascending and descending horizontal displacement vector. The fault trace is also showed

a range increment of 1.5 cm (going from the outer to the inner fringes). The maximum ground displacement measured along the satellite LOS (i.e., $\sim 36^\circ$ from nadir) reaches 18 cm at about 4 km SE from L'Aquila.

Concerning Envisat, two image pairs have been used, so that the coseismic displacements have been detected and measured from two different LOSs. Indeed a first interferogram (post-seismic image dated April 12) along descending orbit measured ten fringes (each 2.8 cm of fringe increment, total 28 cm), while in the Envisat

ascending interferogram (post-earthquake image dates April 15) nine fringes only (maximum displacement ~ 23 cm) probably due to signal loss. It is worth noting the different LOS incidence angles (angle from nadir, or from the vertical to the surface), $\sim 36^\circ$ versus $\sim 23^\circ$. Finally 2 weeks later (April 22), ALOS measured about 24–26-cm displacement (each fringe 11.5 cm of fringe increment) along $\sim 38^\circ$ from nadir. The surface movement is predominantly along a vertical axis, as expected, being originated from a southwest dipping normal faulting mechanism.

In order to explain the geometry and mechanism of the fault, a nonlinear inversion to constrain the fault geometries with uniform slip, followed by a linear inversion to retrieve the slip distribution on the fault plane, has been applied (Fig. 10). The input dataset to the modeling algorithm is composed of DInSAR data plus 30 GPS permanent stations that provided the horizontal vectors. The fault model from geodetic data well defines the position and geometry of the seismogenic fault, identified with the Paganica fault. The additional information provided from DInSAR to standard in situ data and ground surveys is absolutely relevant to the seismological analyses of the earthquake. The large number of SAR images spanning the mainshock recorded the coseismic surface displacement pattern in great detail. The most important results obtained from SAR data were the fast identification and characterization of the earthquake source, i.e., the Paganica fault, indeed previously overlooked as a possible source of a large earthquake. In addition, COSMO-SkyMed data, thanks to the use of a high-resolution (5-m) digital elevation model (DEM), detected local gravitational slope failures reactivated by the mainshock (Moro et al. 2011) where small (4–5-cm) deformations were measured. The L'Aquila sequence is today the only one where three SAR datasets from three different wavelengths have been used.

Tohoku-Oki (2011)

The disastrous Tohoku-Oki megathrust earthquake (M 9.0) occurred on March 11, 2011 (05:46:23 UTC), near the NE coast of Honshu island (Japan). The megathrust earthquake (M 9.0)

Remote Sensing in Seismology: An Overview, Fig. 8 (a) Unwrapped phase from the coseismic interferogram (Fig. 6, left). The city of Bam and Bavarat village

are in black, together with the near field of fault, (b) synthetic interferogram from (a). The white line is the surface trace of the modeled fault, (c) residual map

Remote Sensing in Seismology: An Overview, Fig. 9 Four differential interferograms obtained for the analysis of coseismic displacement of L'Aquila earthquake: (a) COSMO-SkyMed along ascending orbit; (b)

Envisat along descending orbit; (c) Envisat along ascending orbit; and (d) ALOS along ascending orbit. The study area is the red square in the top right inset (From Stramondo et al. 2011b)

originated from a thrust fault on the subduction zone plate boundary between the Pacific and North American plates (Liu and Yamazaki 2013), whose relative motion is 8–8.5 cm/year. The mainshock was preceded by a foreshock sequence lasting two days with a major event on March 9 (Mw 7.3), occurred along the same low-angle thrust plane and about 45 km away of the mainshock (Ide et al. 2011). Although the epicenter is offshore, located about 130 km E of Sendai at about 32-km depth, large coseismic deformation has been detected on land based on GEONET (GPS Earth Observation Network System). Indeed GPS station at the Oshika Peninsula registered up to 5 m toward ESE and 1 m

downward. In particular PRISM and AVNIR are two optical sensors that are not discussed in the manuscript (differently from PALSAR, for instance). A large tsunami estimated more than 10 m followed the seism and reached a few km inland causing serious damage to humans and buildings along the coastline (Watanabe et al. 2012). Maximum run-up heights up to 39.7 m were reported from the Sanriku region. The satellite Earth observation community has focused its attention on the investigation of the surface effects based on satellite data exploitation, in order to measure the surface displacement pattern, the surface changes due to damage, and the coastal changes due to inundation. The focal region from

Remote Sensing in Seismology: An Overview, Fig. 10 (left) Data, (middle) model, and (right) residual interferograms for Envisat (top) descending track 079 (dates: September 02, 2001–September, 04, 2012) and (bottom) ascending track 129 (dates: September 03, 2011–September 04, 2015), with the fault rupture modeled as a uniform dislocation in an elastic medium.

The white line in the interferograms is the up-dip surface projection of our model fault plane. All interferograms are overlain on SRTM topography illuminated from the NE. RMS misfit values for descending and ascending uniform slip models are 1.2 and 1.0 cm, respectively (From Walters et al. 2009)

seismological analysis indicated an area of about 500×200 km moved with a maximum displacement of about 24 m near the hypocenter. Soon after the earthquake, most of the space agencies made their satellite data of the epicentral region available free of charge via the Geohazards Supersites initiative (GEO's Tohoku-Oki Event Supersite Website <http://supersites.earthobservations.org/sendai.php>); JAXA (Japanese Aerospace Exploration Agency), ESA (European Space Agency), DLR (German Space Agency), NASA (National Aeronautics and Space Administration), and CNES (French Space Agency) provided a large number of SAR and optical images even though each agency has different data distribution policies (GEO's Tohoku-Oki Event Supersite Website). A huge dataset of SAR images has been made

available soon after the Tohoku-Oki earthquake thanks to the Group on Earth Observations (GEO) Geohazards Supersites initiative that decided to open the *Tohoku-Oki Event Supersite*.

The main rule to select a Supersite is that “access to spaceborne and in-situ geophysical data of selected sites” is provided to the scientific community. Indeed ERS-2, ASAR Envisat, ALOS PALSAR, TerraSAR-X, and COSMO-SkyMed data have covered the epicentral region. Although such large amount of acquisitions, Envisat and ALOS were the only two satellites able to fully cover the whole earthquake area.

The coseismic interferograms from the 2011 Tohoku-Oki earthquake show a great amount of surface deformation over all of northeastern Japan with a maximum line-of-sight

Remote Sensing in Seismology: An Overview,
Fig. 11 Map of coseismic displacements in Honshu island from Envisat ASAR data. Envisat images are all in IS6 mode, which means they are characterized by an

incidence angle of 40° at the center of each frame (or swath), along descending orbits. The red star indicates the epicenter and red arrows azimuth and range LOS vectors (From Stramondo 2013)

displacement of up to 3.7 m from the ascending PALSAR tracks and 2.4 m from the descending ASAR tracks (Fig. 11), respectively (Feng et al, 2011; Feng and Jónsson 2012). Such a large discrepancy is ascribable to the large horizontal motions, particularly in the eastern component (up to 5.03 m at GPS station 0550), and the large incidence angle. However, because the slip on the subduction interface was at a large distance from the onshore geodetic observations, the InSAR data contribute little new information in Japan, where ground-based GNSS observations are dense (Feng and Jónsson 2012). Nevertheless, the localized deformation due to M 6–7 aftershocks could be measured. In countries where dense GPS are not available, InSAR data alone can be used to invert for the slip distribution on the subduction interface

(Feng and Jónsson 2012; Pritchard et al. 2006; Kyriakopoulos et al. 2013).

New Zealand (2011)

The towns of Darfield (Canterbury) and Christchurch in New Zealand were hit by strong earthquakes within a time span of a few months, in September 2010 and February 2011. The Mw 7.1 Darfield earthquake took place on September 3, 2010, followed by a sequence of large aftershocks to the east, up to the occurrence of the Mw 6.3 Christchurch earthquake on February 21, 2011 (Fig. 12) (Beavan et al. 2010). The Darfield (Canterbury) earthquake occurred along a previously unrecognized east–west fault line, the strike-slip Greendale fault (Beavan et al. 2010; Stramondo et al. 2011b), that DInSAR allowed to detect and characterize.

The hypocenter of the Christchurch event was approximately 6 km southeast of Christchurch's city center, at a depth of 5–6 km, at the easternmost limit of the Darfield aftershocks.

One of the main topics in such case is identifying the possible cause-and-effect relationship, due to the stress transfer, between the September and the February main events. The research in the last decades demonstrated that over major active faults or fault systems, where seismologists registered the occurrence of an earthquake, the probability of occurrence of a second shock increases or decreases according to stress changes 1–4. Indeed, a mainshock perturbs the stress state in other sections of the same fault or in adjacent faults: this theory is known as Coulomb Stress Triggering.

The hypothesis is that once an earthquake occurs, the stress does not dissipate, but it propagates in the surrounding area, where it may increase the probability of occurrence of further earthquakes. In other words, the question is: do earthquakes interact with each other?

In both earthquakes DInSAR technique has been applied to ALOS PALSAR images. The Darfield earthquake led to an average displacement of 2.5 m, up to a maximum of 5 m. Stemming from DInSAR map of surface displacements, the seismogenic fault (Greendale fault) resulted a 44-km-long structure, with some minor lateral branches (see Fig. 12). Conversely, the Christchurch earthquake produced much minor deformation at the surface (average 50 cm), but the fault exactly crossed the city of Christchurch, so that strong damages and casualties were recorded.

In order to verify the hypothesis that an interaction between these earthquakes may have occurred and to understand the role of the first earthquake in promoting the rupture of the second event, the Coulomb failure function (CFF) has been evaluated onto the Christchurch fault plane. The CFF is obtained by computing the stress tensor corresponding to the elastic dislocation induced by the Darfield earthquake, projecting it onto the fault plane of the Christchurch earthquake, and evaluating the relative weights of the stress components (normal and shear), assuming an certain friction coefficient.

Positive or negative variations of the CFF indicate that the stress field is acting to promote or oppose the rupture, respectively. In our case study, the rupture of the 2010 Darfield earthquake loaded a large portion of the crust with stress values exceeding 1 bar. Taking into account the three-dimensional location of the Christchurch rupture plane (Fig. 13), it is clear that the shallower part of the fault (down to about 5-km depth) has actually been unloaded by the Darfield earthquake. The average CFF value on the loaded portion of the Christchurch fault is over 0.01 MPa, with peak values exceeding 0.03 MPa. These stress levels are definitely non-negligible, since a stress value of the order of 0.01 MPa is considered a threshold for effective triggering of seismic events. The stress perturbation due to the Darfield earthquake onto the Christchurch fault promoted the second earthquake, even though without a clear knowledge of the starting stress level of the second fault, it cannot be stated whether this latter was (or not) already likely to occur (Stramondo et al. 2011b).

Summary

In this entry the use of remote sensing in seismology, and in particular the investigation of surface displacements due to earthquakes, has been described. The first paragraph has been dedicated to provide a short overview of SAR satellite missions since the first ever used for soil applications up to the new generation of high-resolution SAR systems. The following paragraph has been concerning the introduction of the use of differential interferometric synthetic aperture radar (DInSAR) technique, a SAR data processing method that exploits the capability of satellite radar images to measure distance changes between satellite and ground surface with centimetric accuracy, for coseismic studies. The main part of the entry concerns the description of case studies relevant to the main topics, covering the time span from the first ever seismological application of DInSAR (Landers earthquake, 1993, see Massonnet et al. 1993).

Remote Sensing in Seismology: An Overview, Fig. 12 Unwrapped interferograms in LOS geometry. *Red stars* are the hypocenter location (from CMT) of the two events. Focal mechanisms are also shown (From Stramondo et al. 2011b)

Remote Sensing in Seismology: An Overview, Fig. 13 A 3D perspective view for the fault model of Greendale fault and Christchurch earthquake fault. In Greendale red and black stars indicate the hypocenter of the two earthquakes, respectively. Both fault the largest slip (about 6.5 m) is concentrated in the middle segment from 0- to 6-km depth. Coulomb stress change is estimated for the Christchurch fault plane. The panels are in UTM WGS84 coordinate system (From Stramondo et al. 2011b)

Residual Strength of Liquefied Soils

Scott M. Olson

Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, USA

Synonyms

Critical state shear strength; Liquefied shear strength; Residual shear strength; Shear strength of liquefied soil; Steady state shear strength

Introduction

Liquefaction flow slides are one of the most catastrophic forms of ground failure. Flow failures often result in massive lateral and vertical movements of soil, occasionally for hundreds of meters laterally. While most commonly observed during earthquakes as a result of seismically induced liquefaction, flow failures also have occurred as a result of non-seismic (static) loading, displacements (i.e., shear strains) induced by global instability or creep, and dynamic loading. These failures are driven by static shear stresses that exceed the available shear resistance in the soil after the soil liquefies. The available shear

resistance after the soil liquefies, or residual shear strength of the liquefied soil, often is only a fraction of the drained shear strength of the soil. Despite the importance of the residual shear strength in analyzing and mitigating the potential for liquefaction flow failure, estimating this strength remains a difficult and controversial issue for geotechnical engineers. Difficulties largely stem from the inability to cost-effectively retrieve undisturbed samples of loose (i.e., contractive), saturated sandy soils that are most prone to liquefaction flow failure. As a result, empirical procedures constitute the state of practice for estimating the residual strength of liquefied soils, evaluating liquefaction flow failures, and designing remedial measures.

This entry reviews the basic definition of the residual shear strength of liquefied soil and the underlying mechanics that control its mobilization, describes failure mechanisms where the residual shear strength of liquefied soil is mobilized, presents a compilation of residual shear strength measurements from a large laboratory database, and illustrates back-analysis procedures used to interpret residual shear strengths from liquefaction case histories and the resulting empirical correlations that are widely used in practice to estimate site-specific values of the residual shear strength of liquefied soils.

Shear Strength of Liquefied Soil

Basic Behavior and Definitions

The residual shear strength of liquefied soil, or liquefied shear strength [$s_u(\text{liq})$], is defined as the shear strength mobilized at large displacement after liquefaction is triggered in a saturated, contractive, cohesionless (i.e., sandy) soil. In the laboratory, where drainage conditions are controlled, the term undrained (or constant volume) applies. However, some flow failures may experience porewater pressure redistribution or drainage (Stark and Mesri 1992; Fiegel and Kutler 1994; Kulasingam et al. 2004); therefore, the shear strength mobilized in the field may not be undrained. The term liquefied shear strength is used to describe the shear strength actually

Residual Strength of Liquefied Soils,

stress; $s_u(\min)$, minimum shear strength; $s_u(\text{critical})$, critical state shear strength; $s_u(\text{yield})$, yield shear strength; ϵ_1 , ϵ_3 , major and minor principal strains (After Olson and Mattson 2008; with permission from Canadian Science Publishing)

mobilized during flow liquefaction, including any potential effects of porewater pressure redistribution/drainage, soil mixing, hydroplaning, etc. Other terms, such as undrained steady state strength (s_{us} , Poulos 1981), undrained residual strength (s_{ur} , Seed and Harder 1990), and mobilized undrained critical strength ($s_u(\text{critical}, \text{mob})$, Stark and Mesri 1992), also have been used to describe the strength of liquefied soil mobilized in the field and in the laboratory. The term liquefied shear strength will be used here.

The liquefied shear strength represents just one aspect of undrained soil behavior. Figure 1 illustrates the response of three saturated Toyoura sand specimens monotonically loaded in undrained triaxial compression. As will be discussed in section “Critical State Framework,” the response of a sand depends on its state (consolidated void ratio and effective stress). Contractive response (or, more specifically, the tendency for contractive response during undrained loading) can be described as the sand

strain-hardens upon initial loading until reaching its yield (or peak) shear resistance; and upon reaching the yield shear resistance, the sand liquefies and strain-softens to a minimum shear resistance. In this case, the minimum shear resistance corresponds to the critical state shear strength, $s_u(\text{critical})$, as defined by Terzaghi et al. (1996) or the undrained steady state shear strength, s_{us} , as defined by Poulos (1981). Contractive undrained response occurs in very loose cohesionless soils and is of primary interest in liquefaction evaluation.

Contractive then dilative (tendency) response is commonly encountered in undrained laboratory testing of sandy soils. This response is similar to contractive undrained response, except that upon reaching a minimum shear resistance, the sand strain-hardens. Alarcon-Guzman et al. (1988) termed this minimum shear resistance the quasi-steady state shear strength based on steady state flow concepts (Poulos 1981); thus, the term quasi-critical state shear strength also

Residual Strength of Liquefied Soils, Fig. 2 Schematic undrained stress–strain and stress path response of saturated, contractive sandy soil (From Olson and Stark 2003; with permission from ASCE)

applies. Contractive then dilative undrained response occurs in loose to medium-dense sands and is relevant in liquefaction evaluation.

Dilative (tendency) response consists chiefly of strain-hardening behavior. The specimen reaches neither a yield nor a minimum shear resistance. Similar to the contractive then dilative undrained response, the sand often continues to strain-harden at large strains and may not reach its critical state within the displacement limits of conventional testing equipment. Dilative undrained response occurs in dense sands and generally indicates that the soil is not susceptible to liquefaction flow failure without significant void ratio redistribution, particle damage, or other changes to the soil.

A number of loading scenarios can trigger flow liquefaction where the liquefied shear strength is mobilized. These include (1) static loading, (2) deformation under a sustained shear stress, and (3) dynamic loading, such as seismic shaking. In each case, flow failures can only occur if the shear stress sustained under gravity loading, or static shear stress (τ_{static}), exceeds the liquefied shear strength. Figure 2 illustrates these scenarios, considering an element within a saturated, contractive sandy deposit either within or underlying an embankment during construction. Point A in Fig. 2 represents the prevailing stress and strain conditions in the element. Point A could have been reached by drained, partially drained, or completely undrained loading during embankment construction. During placement of the next fill lift, the element moves from Point

A to Point B, which is located on the yield strength envelope. This step assumes that the drainage boundaries and permeability of the element result in the fill lift causing a temporary undrained condition in the element. Point B represents the maximum shear resistance that the soil element can mobilize under undrained conditions. When the shear stress in this element induced by the embankment attempts to exceed Point B (the yield shear strength), the contractive soil structure yields and collapses, and liquefaction is triggered. The element then moves from Point B to Point C, the liquefied shear strength. Examples of this scenario include the Calaveras Dam and the Jamuna River bridge site failures (Olson 2001; Jefferies and Been 2006).

To illustrate deformation-induced failure, again consider a soil element with stress and strain conditions represented by Point A in Fig. 2. Point A could have been reached by drained, partially drained, or undrained loading, and the static shear stress carried by the element (Point A) is greater than its liquefied shear strength (Point C). In this case, the static shear stress in the soil is large enough to initiate shear strain, creep, or another deformation mechanism within the embankment and/or foundation. If the shear deformation is sufficiently large and element A is temporarily undrained, the element moves horizontally from Point A to Point D, which is located on the yield strength envelope. At Point D, liquefaction is triggered, and the element moves from Point D to Point C, the liquefied shear strength. Examples of this

Residual Strength of Liquefied Soils, Fig. 3 Upstream slope of Calaveras Dam on March 22 and March 23, 1918 (Photos: <http://damsafetyca.blogspot.com/2008/05/424-calaveras-dam.html>)

scenario include the Fort Peck Dam and the Nerlerk berm failures (Olson 2001; Jefferies and Been 2006).

To illustrate dynamic loading-induced flow failure, consider a soil element with stress and strain conditions represented by Point A' in Fig. 2 (this point is not coincident with Point A for clarity only). Point A' could have been reached by drained, partially drained, or undrained loading, and the static shear stress carried by the element (Point A') is greater than its liquefied shear strength (Point C). The element is then subjected to a seismic or dynamic load. If the duration and intensity of the seismic/dynamic load is sufficient to generate porewater pressures that move the element from Point A' to Point E, liquefaction is triggered, and the element moves from Point E to Point C. Examples of this scenario are most numerous in the literature and include seismically induced failures such as Lower San Fernando Dam, Sheffield Dam, and the Kawagishi-cho apartment buildings and dynamic loading-induced failures such as Asele road embankment and Lake Ackerman highway embankment (Olson 2001; Jefferies and Been 2006).

Examples and Applications

As discussed in section “Basic Behavior and Definitions,” the liquefied shear strength can be mobilized in a variety of loading scenarios, including static loading-induced, deformation-induced, and

dynamic loading-induced failures. Mobilization of the liquefied shear strength requires large shear displacements and can result in liquefaction flow failure, loss of bearing capacity, and lateral soil flow around foundations. Figures 3 and 4 present examples of static loading-induced flow failures experienced at Calaveras Dam and the Jamuna River bridge site, respectively. The 1918 Calaveras Dam failure involved a massive flow failure of the hydraulic fill dam during construction. Rapid filling and a rising phreatic surface likely triggered liquefaction within the uncompacted sandy fills (Olson 2001; Jefferies and Been 2006). The 1995 failures at the Jamuna River bridge site were triggered by rapid cuts and large seepage pressures in the fine micaceous riverbed sands (Yoshimine et al. 1999; Jefferies and Been 2006; Ishihara 2008).

Figures 5 and 6 present examples of deformation-induced and dynamic loading-induced failures at Fort Peck Dam and Lake Ackerman highway embankment, respectively. Although failure occurred during construction, the liquefaction flow failure of Fort Peck Dam likely was triggered by global deformation, as the crest of the hydraulic fill dam had settled over 0.5 m in just a few hours prior to the upstream slope failure. This global movement was attributed to sliding along bentonitic shales in the foundation (Casagrande 1965). Liquefaction of the loose, end-dumped sandy fills at the Lake Ackerman highway embankment was triggered

during a 1990 seismic refraction study, resulting in a large flow slide into the lake (Hryciw et al. 1990).

Figures 7 and 8 present examples of seismic loading-induced failures of the Lower San Fernando Dam during the 1971 San Fernando earthquake and the Las Palmas tailings dam during the 2010 Chile earthquake. While the triggering mechanism among these failures differs, the pre-liquefaction static shear stress exceeded the liquefied shear strength in each case. As a result, once liquefaction was triggered, the failure mass began to accelerate downslope and displacements began to accumulate. In many of these cases, the shear strain within the liquefied material greatly exceeded 100 %.

While failures of embankments and dams are most commonly associated with the liquefied shear strength, the significant loss of shear resistance resulting from liquefaction can lead to bearing capacity failures of foundations. Figure 9

illustrates examples of bearing capacity failures resulting from liquefaction of the foundation soils during the 1964 Niigata, 1999 Dulce, 1999 Ismit, and 2010 Haiti earthquakes. While these bearing capacity failures do not involve displacements of the magnitude observed in many flow failures, the shear strains within the liquefied materials likely exceeded 50 %. Furthermore, in each of these cases, the static shear stresses resulting from the applied bearing pressures exceeded the liquefied shear strength in the saturated, contractive foundation soils.

Liquefaction-induced lateral spreading commonly occurs in mildly sloping ground and is the most common form of liquefaction-induced ground failure. Conventionally, lateral spreads are driven by combined static shear stresses and seismically induced shear stresses exceeding the available shear resistance. Because the failure is largely driven by seismic shear stresses, downslope displacements tend to accumulate in a

Residual Strength of Liquefied Soils, Fig. 9 Liquefaction-induced bearing capacity failures of buildings during several earthquakes: (a) 1964 Niigata (Photo: <http://www.ce.washington.edu/~liquefaction>), (b)

1999 Dulce (Photo: http://www.geerassociation.org/GEER_Post%20EQ%20Reports/Duzce_1999), (c) 1999 Ismit (Photo: <http://www.seas.ucla.edu/~wallace/earthquakes.htm>), and (d) 2010 Haiti

ratcheting manner, with displacements occurring when the seismic shear stresses are oriented downslope. Because the static shear stress is less than the liquefied shear strength, displacements cease when the ground motions end. However, in very loose soils (with very low liquefied shear strengths) or if porewater redistribution results in water layer formation, lateral soil flow can continue after ground motions end. In this case, failure (i.e., continued displacements) is driven by static shear stresses alone. While it is often difficult to differentiate these failure mechanisms, eyewitness reports are occasionally available to identify lateral spreads that continue after the end of shaking. Figure 10 illustrates the failure of the Showa Bridge during the 1964 Niigata earthquake which, according to eyewitness reports, failed as a result of post-shaking lateral flow.

Laboratory Characterization Using Critical State Concepts

Critical state soil mechanics was developed based on Casagrande's (1936) laboratory tests on loose (contractive) sands and the definition of the critical void ratio. The critical void ratio was defined as the prevailing global void ratio when shearing continues under constant shear resistance, constant effective confining stress, and constant volume. By the 1950s, the critical void ratio was redefined as a critical state. In sands, a critical state can occur at large shear displacement where the volume, shear stress, and effective confining stress remain constant (Taylor 1948; Roscoe et al. 1958). This state provides an intrinsic reference state for a sand that depends on its initial consolidated void ratio and consolidation stress, and all shear processes from this initial state eventually reach a critical

Residual Strength of Liquefied Soils, Fig. 10 Post-shaking failure of Showa Bridge during 1964 Niigata as a result of lateral soil flow (Photo: <http://www.ce.washington.edu/~liquefaction>)

state. Critical state soil mechanics is, therefore, a useful framework to understand soil behavior, interpret laboratory test results and field soil behavior, and establish failure criteria and post-failure behavior for constitutive models.

Critical State Framework

The locus of critical states for a given soil defines its critical state line. Figure 11 illustrates the critical state line for Batch 7 silty sand from Lower San Fernando Dam. In void ratio–log effective stress space, the critical state line can be approximated as

$$e_{cs} = e_{cs@1\text{kPa}} - \lambda \log \left(\frac{\sigma'}{1\text{ kPa}} \right) \quad (1)$$

where e_{cs} = critical state void ratio, $e_{cs@1\text{kPa}}$ = critical state void ratio at $\sigma' = 1\text{ kPa}$, λ = critical state line slope, and σ' = effective stress. Soil states after consolidation (i.e., consolidated void ratio, e_c , and consolidation stress, σ'_{vc}) can be compared with the critical state line to determine soil volumetric response to shear. Soil states that are above the critical state line tend to contract during shear, while soil states that are below the critical state line tend to dilate during shear. Been and Jefferies (1985) defined a state parameter, $\psi = e_c - e_{cs}$, to evaluate the potential

dilatancy of a soil. Positive values of state parameter correspond to contractive response, while negative values correspond to dilative response.

In void ratio–log effective vertical stress (σ'_v) space, the consolidated void ratio can be defined using the normal consolidation line or the critical state line as (see Fig. 12):

$$\begin{aligned} e_c &= e_{c@1} - C_c \log \left(\frac{\sigma'_{vc}}{1} \right) \\ &= e_{cs@1} - \lambda \log \left(\frac{\sigma'_{v,cs}}{1} \right) \end{aligned} \quad (2)$$

where $e_{c@1}$ = consolidated void ratio at $\sigma'_v = 1$ unit of stress, C_c = compression index, and σ'_{vc} = vertical consolidation stress. Considering the positions of e_c and e_{cs} along the CSL (see Fig. 12), the state parameter can be defined in terms of effective stresses, using effective vertical stresses here:

$$\begin{aligned} \psi &= e_c - e_{cs} \\ &= \left(e_{cs@1} - \lambda \log \sigma'_{v,cs} \right) \\ &\quad - \left(e_{cs@1} - \lambda \log \sigma'_{vc} \right) \\ &= \lambda \log \frac{\sigma'_{vc}}{\sigma'_{v,cs}} \end{aligned} \quad (3)$$

Residual Strength of Liquefied Soils,

Fig. 13 Relationship between state parameter and liquefied shear strength ratio for five sands in Olson (2001) database.

WRS = well-rounded sand (Data from Konrad 1990), OBS = Ottawa banding sand (Data from Dennis 1988), E330 = Erksak 330/0.7 sand (data from Been et al. 1991), C109 = Ottawa C109 sand (Data from Sasitharan et al. 1993, 1994), Sand B (Data from Castro 1969; Castro and Poulos 1977)

strength can be normalized by effective vertical stress to yield a critical state shear strength ratio:

$$\frac{s_u(\text{critical})}{\sigma'_{vc}} = 10^{-\psi/\lambda} \tan \phi'_{cs}. \quad (7)$$

Thus, the critical state shear strength ratio depends chiefly on the state parameter, the critical state line slope, and the critical state friction angle.

Influence of Soil Characteristics on Critical State (Liquefied) Shear Strength

As shown in Eq. 7, the critical state shear strength depends on the state parameter, critical state line slope, and critical state friction angle. Using a large laboratory test database, Olson (2001) illustrated that $s_u(\text{critical})/\sigma'_{vc}$ is inversely related to ψ (see Fig. 13), confirming the relationship in Eq. 7. However, as also illustrated in Fig. 13, the relationship between $s_u(\text{critical})/\sigma'_{vc}$ and ψ is not unique.

The critical state line slope largely depends on gradation, mineralogy, and particle shape (Poulos 1981). All of these factors are related to compressibility. As such, the critical state line slope tends to increase as compressibility increases (Olson and Stark 2003). The critical state friction angle is chiefly a function of particle surface

roughness, which, in turn, largely depends on mineralogy and particle angularity (Sadrekarimi and Olson 2011). Sadrekarimi and Olson (2011) reported that while the critical state friction angle increases by a few degrees at effective stresses less than about 100 kPa, the friction angle remained nearly constant over a wide range of effective stresses (~100–800 kPa). Therefore, the key factors that influence the critical state shear strength ratio are the initial soil state (as quantified by state parameter, ψ) and the soil compressibility (as quantified by the critical state line slope, λ).

Laboratory-Measured Critical State (Liquefied) Shear Strength Ratios

As illustrated in Fig. 13, the critical state (liquefied) shear strength ratio varies uniquely with state parameter for individual sands. However, for positive values of state parameter (i.e., contractive and contractive then dilative responses), liquefied shear strength ratios vary over similar ranges for many sands with varying gradations and particle shapes. Olson and Mattson (2008) collected a database of 386 laboratory triaxial compression, direct simple shear, rotational shear, and triaxial extension test results to examine yield and liquefied strength ratio concepts.

Residual Strength of Liquefied Soils, Fig. 14 Summary of liquefied strength ratio data for (a) triaxial compression, (b) direct simple shear and rotational shear, and (c) triaxial extension tests. Type A = contractive response, Type B1 = contractive then dilative response where minimum shear resistance is maintained over range of shear strain greater than 3 %, Type

B2 = contractive then dilative response where minimum shear resistance is maintained over range of shear strain less than 3 %, $s_u(ss)$ = steady state shear strength, which is equivalent to critical state shear strength (Modified from Olson and Mattson 2008; with permission from Canadian Science Publishing)

Figure 14 summarizes the liquefied strength ratios measured in these tests. For contractive responses (Type A only), liquefied strength ratios range from 0.01 to 0.23 in undrained triaxial compression, 0.01 to 0.16 in undrained (or constant volume) direct simple shear and rotational shear, and 0.01 to 0.11 in undrained triaxial extension. As anticipated, the Type

B (contractive then dilative responses) tests correspond to specimens with lower state parameters, and therefore these specimens generally exhibit larger liquefied strength ratios than Type A (contractive only) specimens. For the Type A specimens, while the maximum values vary, the average liquefied shear strength ratios are similar for all modes of shear.

Field Characterization from Liquefaction Flow Failures

Critical state soil mechanics theory and laboratory undrained shear tests provide a valuable framework for understanding liquefaction behavior and interpreting flow failures in the field. However, it is difficult to retrieve undisturbed samples of sandy soils that are required for site-specific laboratory testing. While ground freezing has been used successfully to obtain nearly undisturbed samples, this process is too expensive for routine practice (and thus has rarely been used). Furthermore, as discussed in section “[Basic Behavior and Definitions](#),” many flow failures may experience porewater pressure redistribution or drainage; therefore, the shear strength mobilized in the field may not be undrained. As a result of these factors, liquefied shear strengths interpreted from field case histories of flow failures are commonly used to estimate site-specific liquefied shear strengths.

Back-Analysis from Liquefaction Flow Failures

Investigators typically have used three types of stability analyses (of increasing complexity) to back-calculate liquefied shear strengths and strength ratios from liquefaction flow failures. The analysis type depended on the detail and quality of information (e.g., pre- and post-failure geometries, phreatic surface location, sliding surface location, material that liquefied, eyewitness observations) available for each case history. For cases with minimal available information, an infinite slope-type analysis commonly is employed. For cases with sufficient information, a rigorous limit equilibrium analysis is employed. However, a limit equilibrium back-analysis of the pre-failure geometry (assuming a factor of safety of unity) results in an unconservative (too high) estimate of liquefied shear strength because, for the flow slide to occur, the liquefied shear strength had to be less than the back-calculated shear resistance. As a result, limit equilibrium analyses are commonly performed for the post-failure geometry. Figure 15 presents an example of a limit equilibrium analysis performed by

Olson (2001) to back-calculate the liquefied shear strength ratio for the 1971 liquefaction failure of Lower San Fernando Dam.

For cases with appropriate documentation and failure conditions, an additional kinetics analysis can be conducted. As noted above, liquefaction flow failures only occur if the static shear stress exceeds the liquefied shear strength. Because of this, as the failure mass starts to move, its velocity increases. When the failure mass deforms (i.e., moves downslope) sufficiently such that the static shear stress equals the liquefied shear strength, the mass has a finite velocity and will continue to deform and displace. Continued deformation decreases the static shear stress, and the mass decelerates. When the failure mass comes to rest, the static stress often is smaller than the liquefied shear strength, resulting in a factor of safety that is greater than unity. As a result, a limit equilibrium back-analysis of the post-failure geometry that assumes a factor of safety equal to unity results in a conservative (too low) estimate of liquefied shear strength. A kinetics analysis accounts for momentum in the back-analysis and generally is considered to yield the most reasonable back-calculated values of liquefied shear strength and strength ratio.

Correlations Based on Back-Analyzed Field Case Histories

Seed (1987) first proposed to back-analyze liquefaction failures to estimate liquefied shear strengths. However, as discussed by Olson and Stark (2002), there were a few limitations and inconsistencies in the back-analyses performed by Seed (1987). Seed and Harder (1990) expanded the work by Seed (1987), and their resulting correlation is still used in practice. Olson (2001) nearly doubled the number of back-analyzed case histories (from 17 to 33) used by Seed and Harder (1990) and performed kinetics analysis for 10 of the 33 case histories with sufficient documentation. This database has been widely used by numerous researchers (e.g., Idriss and Boulanger 2007; Robertson 2010) for evaluating liquefied shear strengths and strength ratios.

To estimate liquefied shear strengths or strength ratios for specific sites, Seed (1987)

Residual Strength of Liquefied Soils, Fig. 15 Example limit equilibrium analysis of Lower San Fernando Dam to back-calculate liquefied strength ratio. (a) Simplified pre-failure geometry used to determine pre-failure effective vertical stresses with initial failure sliding surface from Castro et al. (1989), and (b) simplified post-failure geometry and assumed final positions of liquefied soil segments (segments 1–9) (From Olsson and Stark 2002; with permission from Canadian Science Publishing)

Residual Strength of Liquefied Soils, Fig. 16 Seed and Harder (1990) relationship between liquefied shear strength and equivalent clean sand normalized SPT blow count (Modified from Seed and Harder 1990)

indexed the field case histories using standard penetration test (SPT) blow count. Furthermore, Seed (1987) proposed to adjust the overburden stress-normalized SPT blow count, $(N_1)_{60}$, for the presence of fines. This fines content-adjusted, overburden stress-normalized SPT blow count was termed the equivalent clean sand normalized blow count, $(N_1)_{60cs}$. Other researchers have used cone penetration test (CPT) tip resistance to index the field case histories. Correlations between liquefied shear strength (or strength ratio) and penetration resistance have been proposed because both liquefied shear strength and penetration resistance are functions of soil density and consolidation stress.

Figure 16 presents a correlation proposed by Seed and Harder (1990) between liquefied shear strength and $(N_1)_{60cs}$ based on the back-analysis of 17 liquefaction flow failures and liquefaction-induced lateral spreads. Seed and Harder (1990) updated the work from Seed (1987), adding a few case histories and considering the kinetics of failure for an unknown number of cases. This correlation remains widely used in practice for estimating the liquefied shear strength.

Figure 17 presents correlations proposed by Olson and Stark (2002) between liquefied shear strength ratio and $(N_1)_{60}$ and overburden stress-

normalized CPT tip resistance, q_{c1} . Olson and Stark (2002) did not include a fines content adjustment for penetration resistance, indicating that the liquefied shear strength ratios shown in Fig. 17 did not exhibit any trend with respect to fines content. They suggested that although soils with higher fines contents should exhibit lower values of penetration resistance (as a result of greater soil compressibility and smaller hydraulic conductivity), these soils are more likely to maintain an undrained condition during flow. The combination of these factors may, in effect, offset each other, resulting in no apparent difference in values of liquefied strength ratio for cases of clean sands and sands with higher fines contents.

Although the Olson and Stark (2002) correlations are linear, the relationships are not intended to be extrapolated indefinitely. These correlations were developed for contractive soils that mobilize a liquefied shear strength. As shown in Fig. 18, Olson and Stark (2003) proposed contractive–dilative boundaries for clean sands that limit the penetration resistance to which the liquefied shear strength ratio correlations can be extrapolated. For example, the CPT-based correlation in Fig. 17b is limited to $q_{c1} \leq 6.7$ MPa for $\sigma'_v = 100$ kPa, $q_{c1} \leq 7.7$ MPa for $\sigma'_v = 200$ kPa, and $q_{c1} \leq 8.4$ MPa for $\sigma'_v = 300$ kPa.

Residual Strength of Liquefied Soils, Fig. 17 Olson and Stark (2002) relationships between liquefied shear strength ratio and normalized SPT blow count and normalized CPT tip resistance (Modified from Olson and Stark 2002; with permission from Canadian Science Publishing)

Residual Strength of Liquefied Soils, Fig. 18 Olson and Stark (2003) relationships between liquefied shear strength ratio and normalized SPT blow count and

normalized CPT tip resistance (Modified from Olson and Stark 2003; with permission from ASCE)

Penetration resistance values higher than these contractive–dilative limits correspond to soils with a dilative undrained response where the undrained shear strength increases dramatically. For cases with penetration resistances that correspond to dilative conditions (in Fig. 18), Olson and Stark (2003) recommended that the mobilized shear strength be defined by the drained shear strength of the soil.

Idriss and Boulanger (2007) combined the back-analyses performed by Seed (1987), Seed and Harder (1990), and Olson and Stark (2002) and proposed correlations between liquefied shear strength and $(N_1)_{60-cs}$, liquefied shear strength ratio and $(N_1)_{60-cs}$, and liquefied shear strength ratio and q_{c1-cs} . Figure 19 presents these correlations. Idriss and Boulanger (2007) attempted to account for the potential for void ratio redistribution (i.e., water layer formation) by recommending conservative correlations for liquefied shear strength ratio, as shown in Fig. 19b and c. They also recommended that the

liquefied shear strength (or strength ratio) be limited to the drained shear strength of the soil.

Robertson (2010) added three flow failure case histories to the Olson and Stark (2002) database and proposed a correlation that utilizes cone penetration test measurements (normalized net tip resistance, Q_{tn} , and normalized friction ratio, F_r) to define a contractive–dilative boundary and a correlation to estimate liquefied strength ratio using equivalent clean sand normalized net tip resistance, $Q_{tn,cs}$. These correlations are shown in Fig. 20. Robertson (2010) also recommended that the liquefied shear strength be limited to the drained shear strength of the soil.

Comparison to Laboratory Measurements

As noted above, the Olson and Stark (2002) back-analyses yielded liquefied shear strength ratios that ranged from approximately 0.05 to 0.12. Figure 21 compares the liquefied strength ratios back-calculated from field case histories with the values

Residual Strength of Liquefied Soils, Fig. 19 Idriss and Boulanger (2007) relationships between (a) liquefied shear strength and $(N_1)_{60cs}$, (b) liquefied shear strength ratio and $(N_1)_{60cs}$, and (c) liquefied shear strength ratio and q_{c1-cs} (Modified from Idriss and Boulanger 2007)

Residual Strength of Liquefied Soils, Fig. 20 Robertson (2010) relationships: (a) CPT-based contractive–dilative boundary and (b) liquefied shear strength ratio and $Q_{tn,cs}$ (Modified from Robertson 2010)

Residual Strength of Liquefied Soils, Fig. 21 Comparison of liquefied strength ratios for field and laboratory data. Flow failure case histories from Olson and Stark (2002). Laboratory data include only Type A (contractive) response where

$s_u(\text{liq}) = s_u(\text{critical})$. DSS direct simple shear, RS rotational shear, TxE triaxial extension, TxC triaxial compression (From Olson and Mattson 2008; with permission from Canadian Science Publishing)

obtained from the Olson and Mattson (2008) laboratory database. This comparison includes only the contractive undrained response (termed Type A) laboratory data because these tests reached unambiguous critical state strengths.

As illustrated in Fig. 21, the laboratory data envelope the case histories, and several case histories exhibit liquefied strength ratios larger than the upper bound for triaxial extension tests. This suggests that a triaxial extension mode of shear did not dominate liquefaction flow in these cases. Furthermore, the range of liquefied strength ratios mobilized in the field cases (0.05–0.12) is relatively small compared to the laboratory ranges, particularly the triaxial compression liquefied strength ratios (0.01–0.23). Importantly, the liquefied shear strengths mobilized in the field cases fall near the middle of the range for the direct simple/rotational modes of shear, supporting the use of effective vertical stress for liquefied shear strength normalization.

Summary

The residual strength of liquefied soil, or liquefied shear strength, is defined as the shear strength mobilized at large displacement after liquefaction

is triggered in a saturated, contractive, cohesionless (i.e., sandy) soil. While this definition is relatively straightforward, estimating the liquefied shear strength in practice remains a difficult task. This largely stems from the high cost and difficulty in retrieving high-quality, undisturbed samples of contractive, saturated sandy soils, as well as ongoing controversy regarding how the liquefied shear strength and critical state line should be determined.

As a result, the standard of practice for estimating the liquefied shear strength is using empirical correlations where liquefied shear strengths or strength ratios (liquefied shear strength divided by effective vertical stress) have been back-calculated from liquefaction failures. In these relationships, back-calculated liquefied shear strengths are correlated to measured or estimated standard or cone penetration test results. However, as a result of uncertainties related to a lack of well-documented case histories, as well as judgments related to the back-analyses and various interpretations of penetration resistance, a number of empirical estimates of liquefied shear strength and strength ratio are available in the literature. These correlations, while widely used in practice, require further research and validation.

Adaptive; Community resilience; Economic resilience; Individual resilience; Organizational resilience; Planning; Preparedness; Recover; Recovery; Response; Vulnerability

Introduction

Resilience to earthquake disasters should be a goal of any community living in a seismically active landscape. Resilience is the ability to not only survive but also to thrive in the face of adversity – in this case an earthquake. There are many aspects to achieving a resilient community. This entry will first explore the concept of resilience and the use of the term by different disciplines. It then goes on to look at the different systemic layers of resilience that are needed to achieve resilience to earthquake disasters, using examples from the Christchurch, New Zealand, 2010/2011 earthquakes to illustrate. The final

section of the entry looks at opportunities for improving resilience to earthquake disasters.

This entry serves as an introduction to the Disaster Recovery, Reconstruction, and Loss Modeling section of the Encyclopedia of Earthquake Engineering. Throughout the entry, readers are referred to other papers within the section where more information can be found on particular topics.

What is Resilience?

The recent popularity of the word resilience has led to diverse applications of the term – resilience seems at times to mean everything to everyone. Within the literature, there are many definitions of resilience, a selection of which are represented in Table 1. Why so many different definitions? The primary reason is that different disciplines use terms in ways that are pertinent to their field of study, both from a content and from a unit of analysis standpoint. In addition, some definitions and disciplines may take a process focus while others take an outcomes focus or speed of outcomes focus to viewing resilience. For example, ecology is concerned with the populations in the ecosystem and their ability to absorb change, while sociology and engineering are concerned with social and physical systems, respectively, and their ability to respond when disruption occurs.

In spite of the differences, however, there are many commonalities to the definitions of resilience provided in the literature. Virtually all of the definitions have certain characteristics in common:

- Resilience is a feature of a system (physical or social).
- The system is able to respond to change, disruption, or hazards through resistance, absorption, or adaptation or a combination of these.
- The system is able to continue to function at some level following the disruption: returning to its original state or potentially an adapted and improved state.

So although the language may vary by discipline, the fundamentals are largely the same.

Resilience to Earthquake Disasters, Table 1 Definitions of resilience from different disciplines (Kachali 2013)

Author(s)	Academic/research discipline	Definition
Holling	Ecology	A measure of the persistence of systems and of their ability to absorb change and disturbance and still maintain the same relationships between populations or state variables (Holling 1973)
Horne and Orr	Organizational and human resource development	Resilience is a fundamental quality of individuals, groups and organizations, and systems as a whole to respond productively to significant change that disrupts the expected pattern of events without engaging in an extended period of regressive behavior (Horne and Orr 1998)
Perrings	Environmental and resource economics	Resilience is a measure of the ability of a system to withstand stresses and shocks – its ability to persist in an uncertain world (Perrings 1998)
Comfort	Public and international affairs (public policy analysis)	The capacity to adapt existing resources and skills to new systems and operating conditions (Comfort et al. 1999)
Petak	Public administration	The system’s ability to make a smooth transition to a new stable state in response to the disturbance (Petak 2002)
Bruneau et al.	Earthquake engineering (community disaster resilience)	The ability of social units (e.g., organizations, communities) to mitigate hazards, contain the effects of disasters when they occur, and carry out recovery activities in ways that minimize social disruption and mitigate the effects of future earthquakes (Bruneau et al. 2003)
Tierney	Sociology	A property of physical and social systems that enables them to reduce the probability of disaster-induced loss of functionality, respond appropriately when damage and disruption occur, and recover in a timely manner (Tierney 2003)
Christopher and Peck	Logistics	The ability of a system to return to its original state or move to a new more desirable state after being disturbed (Christopher and Peck 2004)
Rose	Economics	The ability or capacity of a system to absorb or cushion against damage or loss. . . (more general definition) that incorporates dynamic considerations, including stability, is the ability of a system to recover from a severe shock (Rose 2004)
Walker et al.	Ecology	The capacity of a system to absorb disturbance and reorganize while undergoing change so as to still retain essentially the same function, structure, identity, and feedbacks (Walker et al. 2004)
Hollnagel et al.	Engineering	The ability of systems to anticipate and adapt to the potential for surprise and failure (Hollnagel et al. 2006)
Seville et al.	Business and engineering	An organization’s ability to survive, and potentially even thrive, in times of crisis (Seville et al. 2008)
UNISDR	Disaster reduction	The ability of a system, community or society exposed to hazards to resist, absorb, accommodate to and recover from the effects of a hazard in a timely and efficient manner, including through the preservation and restoration of its essential basic structures and functions (UNISDR 2009)

Resilience Required at Many Levels

For a community to both survive and be able to thrive following an earthquake, it is important for them to be resilient in all aspects vital to how that community functions. There are many different lenses by which a community’s resilience to

earthquakes could be considered; for the purposes of this entry, the framework in Fig. 1 is used.

Individual Resilience

How can an organization or community be resilient if the individuals that are in it are fragile?

Resilience to Earthquake Disasters,

Fig. 1 Different lenses that can be applied to a community's resilience

Clearly, the resilience of individuals is a key aspect to the resilience of communities and organizations. Individuals with high social capital, an optimistic outlook, good coping skills, sound physical health, and an ability to adapt will have increased levels of resilience. These characteristics can be supported and enabled by the community in which they live through mentoring, wise colleagues at work, hope inspiring leaders, and a community that encourages participation. The resulting community cohesion and a willingness to help each other under stressful circumstances have direct impacts on physical and mental health, stamina, and ability to recover in the aftermath of an earthquake.

Some individuals will have a greater capacity to “bounce back” than others. This capacity is determined by a range of characteristics that make some individuals more resilient and others more vulnerable. The entry “► [Community Recovery Following Earthquake Disasters](#)” highlights the fact that many communities, and the individuals within them, bring certain risk and protective factors to potential disaster situations. This combination of risks and resiliencies interacts with hazard and exposure variables to determine the extent to which each person and the communities of which they are part are affected. Within an affected community, different groups and individuals may experience the disaster in a multitude of ways.

Although most people will experience some psychosocial reaction to a disaster, the majority of people do recover from disaster events, with time and basic supports.

Bonanno et al. (2007) found a series of factors that support resilience in a range of settings, including age, sex, education, circle of friends and family, employment skills, location, and physical and mental health. All of these factors contribute in varying ways to individual resilience.

The Built Environment

The built environment provides shelter, workplace, community facilities, as well as essential infrastructure such as water, waste disposal, power, telecommunications, and transport. A modern community is dependent on this built environment to support the daily social, commercial, and cultural functioning of life. It is also this built environment that takes such a punishment when an earthquake strikes resulting in impassable roads, loss of electricity, “boil-water” notices, and collapsed buildings.

As highlighted in the “► [Damage to Buildings: Modeling](#)” entry, damage to the built environment is the root cause of many consequential impacts of earthquakes on a community. The potential for both structural and nonstructural damage to buildings and their contents leads to the potential for deaths and injuries, direct costs

for repair or replacement of the building and contents, as well as indirect losses that emerge as a result of the disruption caused by the damage.

For infrastructure systems, it is not just the damage to the individual components that is important for understanding community level impacts but also how the whole system consequently performs. As highlighted in the “► [Damage to Infrastructure: Modeling](#)” entry, it is essential also to understand the connections between these components and their spatial distribution relative to urban populations, since some components will be more critical than others in terms of their impact on system performance.

Brunsdon et al. (2013) bring another perspective, suggesting that resilience of the built environment be considered as comprising the following four elements:

- Robust assets capable of maintaining both low damage in more frequent events and life safety in major events
- Planning and preparation for failure, including key components and network routes having appropriate alternatives as well as having effective response arrangements in place
- Effective coordination of regulatory, design, and construction processes, to both ensure quality and to facilitate repair and reconstruction
- Realistic end-user expectations, with both owners and users understanding the risk and performance objectives and appropriate measures of backup arrangements

The key point from these elements is that resilience involves more than just the resilience of physical assets. Improving end-user knowledge of how the built environment is likely to perform in an earthquake, and encouraging users (particularly organizations with emergency response roles such as hospitals) to plan for a level of disruption in extreme events is also essential.

Economy and Organizations

The economy for a community consists of both the economic environment and the organizations

that populate that environment. The laws and regulations, the lack of corruption in government and commercial dealings, the taxation system, critical infrastructure, economic sector critical mass, and the competitive market all contribute to the economic environment. The entries “► [Economic Recovery Following Earthquakes Disasters](#)” and “► [Economic Impact of Seismic Events: Modeling](#)” together provide a detailed analysis of the ways in which earthquakes can affect the functioning of an economy, at both micro- and macro-levels.

Organizations provide employment, goods, and services and gathering places for the individuals within a community. The way in which a community’s organizations function within a disaster-disrupted environment contributes to both the state of economic resilience and the community’s overall resilience. In a disaster such as a large earthquake, organizations provide a rallying point where people can find encouragement from their work colleagues, a distraction from a badly damaged home, and solace from the loss of a loved one.

Organizational resilience can be conceptualized as (1) the adaptive capacity of an organization that is created by leadership and culture, (2) the internal and external relationships and networks that an organization draws on in both business as usual and when a crisis happens, and (3) the planning that is done to develop a clear direction that enables an organization to be change ready (Resilient Organisations 2013). So how does the economic environment support such organizational resilience? An example is given below of the Earthquake Support Subsidy (ESS).

The ESS was a central government initiative that was put in place shortly after the Christchurch earthquakes to provide a wage subsidy for businesses affected by the earthquakes that had fewer than 50 employees (more than 95 % of New Zealand businesses have fewer than 50 employees). The subsidy was provided for 6 weeks, with very low compliance costs to access the subsidy. The subsidy was given directly to the employer so that wages could be paid. The effect of the ESS was to provide time

for employers to get beyond the “fight or flight” stage of earthquake response and to do some forward planning for how they might recover. It provided assurance to employees that they would still be paid. Most importantly, in the critical first few weeks following the earthquakes, it maintained the employer-employee relationship. This initiative prevented the loss of jobs as well as a loss of employers. This in turn meant loss of population was minimized. This juncture of the economic environment and organizations was effective in maintaining economic activity, organizational coherence, and community resilience.

Institutional Resilience

Resilience is also needed within the institutional environment of a community. The institutional environment is the environment in which an individual, a community, or an organization functions and the supporting mechanisms that provide the boundaries for that functioning. The legal frameworks, building codes, political structures, insurance setting, and a range of other institutions and processes all provide this environment. The nature of these institutional arrangements can provide enhanced resilience, resources, and safety or add to the fragility of the wider community. Effective emergency services, a robust banking system, a proactive local council, an honest police force, and the availability of inexpensive earthquake insurance are all examples of institutional resilience.

An exemplar of this from the Christchurch earthquakes is the New Zealand Earthquake Commission (EQC). This quasi-government organization provides an earthquake insurance scheme for residential housing. The insurance is mandatory if the dwelling has fire insurance and as a consequence of the resulting high market penetration (95 % uptake) is very cost-effective. A consequence of this institutional environment is that following the Christchurch earthquakes, 95 % of homes were insured and will be repaired or rebuilt following this devastating event.

Natural Environment

The habitat that a community is situated in has an impact on its overall resilience. Availability of

clean water, fresh air, and uncontaminated land are a few of the things that we take for granted – but are essential to a healthy community which is able to respond effectively in the aftermath of a large earthquake. Following the 2010/2011 earthquake series in Christchurch, New Zealand, there were significant impacts on the natural environment. Substantial liquefaction, lateral spreading, and land subsidence are impacted on both the appearance and livability of some sections of the city. In areas deemed highly prone to liquefaction and lateral spreading, the land was “red zoned” with all houses within these areas slated for demolition, with no permitted re-habitation. In areas of significant land subsidence (in some areas in excess of a half meter), localized flooding has become an endemic problem now requiring judgments on habitability and flood protection.

Further impacts of earthquakes on the natural environment include issues of demolition debris, contaminated liquefaction, and other products of the devastation caused by seismic events. As highlighted in the entry “► [Waste Management Following Earthquake Disaster](#),” effective management of such waste disposal and recycling can either preserve or significantly undermine the natural environment. These impacts on the natural environment have flow on effects on the local population’s health, well-being, and resilience.

Community Resilience

A resilient community is one that can cope with, adapt to, and recover from the loss and disruption encountered through the experience of a disaster. As highlighted in the entry “► [Community Recovery Following Earthquake Disasters](#),” how effectively this is done is a function of how well people, communities, and societies can work together and use their resources to deal with the problems encountered. Resilience of individuals and the built environment, organizations, and the economy of institutions and the natural environment all contribute to the resilience of a community.

Paton and Johnston’s (2006) model of community resilience emphasizes the importance of

community development and participation. Aldrich (2012) asserts that social capital is a critical element of resilience and recovery for a community. Both of these point to the fact that it is the people and their interactions that are at the foundation of community resilience and the ability to recover from disasters. The built environment and economy, the organizations and institutions, and the natural environment are all there as supporting elements of this foundation, but in the end, as an old Maori (New Zealand) saying goes, “it is about the people, the people and the people.”

Improving Resilience

To be resilient to disasters, people, organizations, and communities need to be able to successfully develop both planned and adaptive resilience capabilities (Fig. 2).

Planning is needed to understand and, where possible, to mitigate the potential impacts of an earthquake on a community. Adaptive capabilities are needed to enable the community to respond creatively to the unexpected challenges that inevitably occur when disasters strike. Ideally, communities will hold both planned and adaptive capabilities in equal measure. Communities that fail to plan sufficiently for the risks they face can find themselves in a cycle of “reacting” to potential disasters. Communities that become too rigid in their thinking can restrict their ability to act and to change as circumstances require.

As discussed in the entry “► [Sustained Earthquake Preparedness: Functional, Social, and Cultural Issues](#),” the goal of planning activities should be to increase the likelihood of people and communities being in a position to be able to respond in planned and functional ways to the complex, challenging, emergent challenges and demands that earthquakes create, rather than having to react to them in ad hoc ways. But a community should also see that the benefit of planning comes from skills and capabilities developed through the planning process, rather than the main outcome being a “plan.” They

Resilience to Earthquake Disasters, Fig. 2 Both planned and adaptive capabilities are required for greater resilience

should consciously plan for how to develop their adaptive skills and capabilities – so that if there is a need to “react,” then they can adjust or develop new plans as required.

Planning should cover the 4 R’s of emergency management: reduction, readiness, response, and recovery (also known in some countries as prevention, preparedness, response, and recovery).

One of the first steps for a community in planning for earthquake disasters is to understand the risk to which they are exposed. This encyclopedia includes a number of entries relating to modeling, including ways a community can better understand the level of seismic hazard to which it is exposed using ► [Probabilistic Seismic Hazard Models](#) and how it can model potential impacts on community functions (e.g., “► [Damage to Buildings: Modeling](#),” “► [Damage to Infrastructure: Modeling](#),” and “► [Economic Impact of Seismic Events: Modeling](#)”).

Communities can also plan to be ready to both respond and recover from disaster. The most obvious focus for such planning is around ► [Emergency Response for Earthquake Disasters](#), but there are also other aspects, particularly related to recovery, that also benefit from prior planning. As discussed earlier, damage to the built environment in an earthquake is the root cause of many consequential impacts of earthquakes on a community. Planning for how to deliver an effective and efficient post-disaster reconstruction program is important. There are many different issues to consider in planning for ► [Reconstruction Following Earthquake Disasters](#). Of particular importance is ► [Earthquake](#)

Disaster Recovery: Leadership and Governance. There is also the potential need to change laws and regulations to facilitate a rapid and effective rebuild (► [Legislation Changes Following Earthquake Disasters](#)). In some circumstances, it may also be necessary to reevaluate ► [Land use planning following earthquake disasters](#) to understand if a community “should” rebuild in the same location. There is a need to consider how to deal with waste generated by the earthquake (► [Waste Management Following Earthquake Disaster](#)) and the resourcing implications that a reconstruction might have on the broader economy (► [Resourcing Issues Following Earthquake Disaster](#)).

Reconstruction takes time, in many cases decades, so it is important to also consider the transitional issues likely to emerge while the reconstruction and recovery takes place. For example, there is a need to plan for how to provide interim housing for people whose homes are damaged by the earthquake (► [Interim Housing Provision Following Earthquake Disaster](#)).

Resilience is also about finding the “silver lining” – seeking out the opportunities that always arise during a disaster, with the goal of emerging stronger and better than before. Throughout the literature, there is a concept emerging of the need to not just “bounce back” from disasters but to use disasters as an opportunity to “bounce forward” (Manyena et al. 2011), rebuilding communities to be better and more resilient than before (► [“Build Back Better” Principles for Reconstruction](#)). As earthquake disasters are relatively rare, it can often be difficult to build momentum for mitigation and preparedness activities. It is important therefore to leverage the disasters that do occur to focus collective attention and effort on improving resilience and ► [Learning from Earthquake Disasters](#).

Summary

This entry provides a high level overview of what it takes for a community to become “resilient” to earthquake disasters. Resilience is a term that is used within a number of disciplines,

all with slightly different definitions. At its core though, resilience refers to the ability of a system to be able to respond to change and to be able to continue to function at some level following the disruption. Resilience is not only about being able to survive a disaster but also requires being able to thrive in an ever changing environment. Communities situated in seismically active areas may have little ability to control the frequency or intensity of earthquakes they are exposed to. Communities can however make proactive efforts to reduce their vulnerabilities to earthquakes and to prepare themselves to both respond and recover from earthquakes when they do occur. Our communities need to become resilient to earthquake disasters.

Resiliency of Water, Wastewater, and Inundation Protection Systems

Craig A. Davis

Waterworks Engineer, Los Angeles Department of Water and Power, Los Angeles, CA, USA

Synonyms

Infrastructure service categories; Lifeline system earthquake resilience; Performance objectives; Post-earthquake service restoration

Introduction

Water, wastewater, and inundation protection systems are lifelines critically related to a communities' resilience to earthquakes. Herein, water, wastewater, and inundation protection systems respectively refer to potable water, sanitary sewer, and storm water control and flood protection systems (includes urban drainage, river dam and levee systems, sea wall barriers, etc.). Water, wastewater, and inundation protection systems in modern urban settings are critical for public health and human survival, and their ability to

recover and restore services following an earthquake is essential for community resilience.

Water and wastewater systems are generally well understood and do not require significant defining descriptions. However, inundation protection systems are not as well understood in the context described herein. Impacts from Hurricane Katrina in New Orleans, USA, identified how inundation protection systems serve as community lifelines and the need to understand their systemic performance for community protection. Events in Japan and New Zealand (both in 2011) have identified the critical need for post-earthquake performance of inundation protection systems. Some portions of inundation protection systems such as urban storm water drainage have great similarities with wastewater systems and are sometimes combined with wastewater sewer systems. Other water collection, storage, and conveyance systems are strongly related to water systems. However, the classic understanding of water, wastewater sewer, or storm water sewer systems does not include important aspects of the more general use of inundation protection systems such as water-retaining levees along major rivers and sea barriers protecting cities against atmospheric hazards (hurricane, typhoon, etc.). These are clearly critical lifeline systems and need to address the cascading effects of potential flood after earthquakes in order to properly address the inundation protection system along with the community resilience.

Water, wastewater, and inundation protection systems are large and complex geographically distributed systems traversing many geologic formations and hazards and can experience damage and resulting service losses when subjected to a widespread shock from an earthquake. A lifeline system's seismic resilience is dependent upon the amount of service losses sustained by an earthquake and the time required to return the services. The post-earthquake system performance is critical to the resilience of the communities served.

In order to assess a systems' serviceability and needed resilience following an earthquake and how those services impact community resilience, one must first understand the service types or

categories a system needs to provide after a potentially disastrous event (i.e., service customers have become dependent and reliant upon for personal and community-wide survival and sustainability).

The following section describes performance categories commonly expected of water, wastewater, and inundation protection systems. System services are shown as a subset of the performance categories. Each system performs functions to provide services to customers or portions of communities. For example, water systems have connections from the distribution network to homes or businesses to provide water to each customer. Wastewater systems have connections from homes or businesses to the collection network to remove sewage wastes for each customer. For these two systems each customer has a physical service connection, whereas inundation protection systems do not generally have customer connections as that described for water and wastewater systems. Instead inundation protection systems usually operate infrastructure to protect certain areas from being flooded. These areas may be farm lands, residential neighborhoods, business communities, entire cities, etc. The useful lands being protected are owned and utilized by people, businesses, governments, etc., who, in the context of this entry, are considered customers by the inundation protection system operators. Resilience is discussed in terms of the systems' ability to recover and return services over time and how the customers, and thus the communities, are impacted.

Water, Wastewater, and Inundation Protection System Performances and Services

Table 1 shows three primary system performance categories: (1) water, wastewater, and inundation protection services; (2) life safety; and (3) property protection. The service category is made up of at least five additional categories in Tables 2, 3, and 4, making a total of seven primary performance categories for each system. The total number of system performance categories is not

Resiliency of Water, Wastewater, and Inundation Protection Systems, Table 1 Primary water, wastewater, and inundation protection system performance categories

Performance category	Description
Water, wastewater, and inundation protection services	Provision of water, wastewater, and inundation protection services identified in Tables 2, 3, and 4, respectively
Life safety	Preventing injuries and casualties from direct or indirect damages to system facilities; includes safety matters related to response and restoration activities
Property protection	Preventing property damage as a result of damage to system components; also includes preventing system damages

Resiliency of Water, Wastewater, and Inundation Protection Systems, Table 2 Water service categories

Service categories	Description
Water delivery	The system is able to distribute water to customer service connections, but water delivered may not meet quality standards (requires water purification notice), pre-event volumes (requires water rationing), fire flow requirements (impacting firefighting capabilities), or pre-earthquake functionality (inhibiting system operations)
Quality	The water quality at service connections meets pre-earthquake standards. Potable water meets health standards (water purification notices removed), including minimum pressure requirements to ensure contaminants do not leach into the system
Quantity	Water flow to customer service connections meets pre-earthquake volumes (water rationing removed)
Fire protection	The system is able to provide pressure and flow of a suitable magnitude and duration to fight fires
Functionality	The system functions are performed at pre-earthquake reliability, including pressure (operational constraints resulting from the event have been removed/resolved)

Resiliency of Water, Wastewater, and Inundation Protection Systems, Table 3 Wastewater service categories

Service categories	Description
Wastewater collection/removal	The system is able to collect and remove wastewater at the customer service connections while preventing sewage flooding, but the system may not be able to treat collected wastewater to meet quality standards, properly dispose of wastewater, or meet pre-earthquake functionality (inhibiting system operations)
Quality	Wastewater is able to be treated to pre-earthquake volumes using intended processes and meet public health standards
Disposal	Entire wastewater volume is able to be properly disposed, protecting the environment, and meeting public health standards (including containment within pipe network)
Reclaimed source	Wastewater is able to be treated and used as an alternate source of water supply (note: this does not apply to all wastewater systems)
Functionality	The system functions are performed at pre-earthquake reliability (operational constraints resulting from the event have been removed/resolved)

limited to seven; however, any additional categories utilized to understand water, wastewater, or inundation protection system resilience are likely subordinate and needed to achieve the primary services presented in Tables 2, 3, and 4. Tables 2, 3, and 4 summarize service categories normally

provided by water, wastewater, and inundation protection systems using common network components and topology.

A system or portion of system meeting the description in Tables 2, 3, and 4 for each category is considered restored to the customer.

Resiliency of Water, Wastewater, and Inundation Protection Systems, Table 4 Inundation protection system service categories

Service categories	Description
Flood defense	The system is able to defend regions against flood hazard by collecting, storing, removing, and/or providing hydraulic containment and barriers to protect life and property from storm water and other forms of water runoff (e.g., snowmelt) as well as waves, surges, and other potential forms of inundation from water bodies; but some region(s) may be more vulnerable to flooding than prior to the earthquake and the system may not be able to treat water to meet quality standards, properly utilize or dispose of water, or meet pre-earthquake functionality (inhibiting system operations)
Quality	Water is able to be treated to pre-earthquake conditions using intended processes and meet public health standards (note: this does not apply to all inundation protection systems)
Disposal	Entire wastewater volume is able to be properly disposed, protecting the environment, and meeting public health standards (including containment within pipes, conduits, and conveyance lines)
Water supply	Storm/flood water is able to be treated and used as a water supply source (note: this does not apply to all inundation protection systems)
Functionality	The system functions are performed at pre-earthquake reliability, including the meeting or exceeding of pre-earthquake inundation protection levels (vulnerabilities and operational constraints resulting from the event have been removed/resolved)

The descriptions in Tables 2, 3, and 4, respectively, are intended to capture most aspects associated with modern water, wastewater, and inundation protection system services around the world; however, description modifications may be needed to suit certain regional practices. Some systems may not provide all the services listed in the above tables, but all systems have at least a primary category (e.g., water delivery, wastewater collection, flood defense) and functionality services. Local systems may need to customize Tables 2, 3, and 4 by modifying, removing, or adding services and related descriptions to ensure proper system resilience.

The ability of systems to provide the service categories in Tables 2, 3, and 4 can be assessed at any given time as a ratio of the number of customers with the service after an earthquake to the number of customers having the service before the earthquake. An assessment can be performed in relation to a hazard evaluation or an actual event for each service category in Tables 2, 3, or 4. As exemplified in Fig. 1a–c, the number of customer services restored over time can be monitored to track and evaluate overall system serviceability for each category.

The service restoration curves in Fig. 1a–c do not represent the performance of any specific system following any specific earthquake

scenario; the curves are only intended to aid in understanding service restorations and system resilience. The units of weeks shown on the time axis are not intended to be typical. The restoration curves for each system hold specific characteristics that can be used as management tools for understanding how to develop and manage resilient systems. Davis (2011, 2014b) describes water system service characteristics and their interactions.

The flood defense service category in Table 4 has a related but important difference to the life safety and property protection performance categories in Table 1. The inundation protection systems serve to provide property protection against flooding and most coincidentally provide life safety protection against flooding; thus, the property protection and life safety performance categories are also service categories for the inundation protection systems. However, life safety and property protection issues go beyond the primary inundation protection purpose and include other aspects of system performance and operations, which are covered in the Table 1 performance categories (e.g., building collapse, unsafe work practices, and other examples provided in this entry), but not in the Table 4 flood defense service category.

The provision of services and the protection of life and property are arguably the most important

Resiliency of Water, Wastewater, and Inundation Protection Systems, Fig. 1

(a) Example water service restoration curves. (b) Example wastewater service restoration curves. (c) Example inundation protection service restoration curves

performances the water, wastewater, and inundation protection systems can achieve. Life safety can be threatened when system structures fail, dangerous chemicals (e.g., chlorine) are released into the atmosphere, large volumes of water are catastrophically released into populated areas (e.g., dam or levee failure), etc. Property damage can result from similar system damages as well as water from pipe breaks. Proper hazard mitigations to critical components within a system (e.g., strengthening dams, pipes, and other facilities, anchoring chemical containers, etc.) are important measures to prevent casualties and property damages. Although these mitigations are critical for life and property safety and aid in improving system resilience, they generally focus on specific components within the system and as a result do not always directly improve the ability to provide post-earthquake services. Services are those systemic aspects customers must rely upon, including safe and reliable: (A) water supply as described in Table 2; (B) wastewater collection, disposal, and associated items as described in Table 3; and (C) flood protection and associated items as described in Table 4.

The system serviceability categories can be used as direct measures of system resilience and related to community resilience; as a result, system resilience cannot be measured using a single performance category since no system can be defined with only one service category (there are at least two service categories for every system as described above). In contrast, the life safety and property protection categories are difficult to relate to system resilience as they cannot be used as a metric to track system performance over time, but often can be more directly related to community resilience. All performance categories are important to ensure community resilience, but the service categories are often the most important metrics for understanding water, wastewater, and inundation protection systemic resilience. This can be clarified through examples. If a large dam located within a city fails resulting in extreme devastation to a community, the community may be found to have low resilience to such a hazard (i.e., take an exceptionally long time to recover to pre-dam

failure conditions), but the water system may have high resilience on a systemic level and able to continue providing potable water services (all services shown in Table 2) to all customers (excepting any lost services from the flood) at all times because it has redundant supplies. This example shows the importance of the life safety and property protection performance categories and emphasizes the flood defense service category of inundation protection systems. Now, presume the water system has mitigated the seismic risks to the above described dam so that it does not fail during a great earthquake striking the city, but thousands of other water system components, which do not pose a life safety or property protection concern, are severely damaged removing the ability to supply water to the majority of customers for a very long time, leading to public health concerns. In this second example water supply remains behind the dam, but the system fails and is unable to deliver water. The water system is less resilient to the earthquake than the dam failure hazard, even though the dam failure may be more catastrophic to the community. Certainly the water system and the community are both in worse condition and less resilient if the dam were to fail during the earthquake. From these examples the relative community resilience between the dam failure and earthquake hazards cannot be judged. The main point of these examples is not to weigh the services versus life safety or property protection performance categories, but instead to show how all performance categories are important, and addressing only a few performance categories does not necessarily improve system or community resilience to all important hazards potentially impacting a community.

System Services and Seismic Resilience

McDaniels et al. (2008) illustrates system resilience, shown in Fig. 2, as a measure of system performance over time, describing system performance by the number of customers served. Bruneau et al. (2003) illustrates system resilience similarly describing the vertical axis as the

Resiliency of Water, Wastewater, and Inundation Protection Systems, Fig. 2 Infrastructure system resilience

quality of infrastructure of a community. From this it is easy to see how the water, wastewater, and inundation protection system service restoration curves in Fig. 1 can be linked to resilience. Figure 1 also illustrates how system resilience is more complex than shown by a single curve in Fig. 2. Understanding this complexity is important to: (1) developing, maintaining, and operating a resilient infrastructure system and (2) creating a resilient community.

As previously noted, water, wastewater, and inundation protection system resilience cannot be characterized by any single service category. These system resiliencies are dictated by multiple service categories and how they interact with the regional community. Community dependence on water, sewage disposal, and flood protection for survival does not allow these system's resiliencies to be defined independent of the community resilience. This is compounded by the dependency relationships with other lifeline infrastructure (e.g., power to run pump stations). Thus, system resilience cannot be measured only by the service-time lost, but also by how it helps to improve overall community resilience; this is clarified using some examples below.

Water System Examples

If an urban water system were able to provide nearly full water delivery and quality service throughout the distribution area but limited fire protection service following a major earthquake,

and several ignitions grow into large fires, then this could result in serious community fire damage, especially if the fires merged into a major conflagration. This situation would not be a characteristic of a resilient community, but if only one of the service restorations was reviewed (e.g., water delivery, as is commonly done following an earthquake), the water company could potentially claim that it was highly resilient to the earthquake. As another example, water systems capable of providing post-earthquake services to other lifelines and emergency operations such as hospitals, emergency operation centers, evacuation centers, etc., in a manner that does not significantly disrupt their critical operations help increase the community resilience. This is a characteristic of a resilient water system even if the services to residents and other businesses are temporarily disrupted.

Wastewater System Examples

A wastewater system transmission pipe network located in a large urban area is severely damaged in an earthquake and cannot be used to convey sewage from the customer service connections to the treatment plant. However, most customers can dispose sewage from their buildings into the wastewater collection network directly through their service connection lines, as long as the transmission system can remove the waste and keep it from backing up and flooding the streets and homes. To continue providing collection services, the wastewater system operators begin to dispose of waste directly into local rivers and streams passing through the city. This allows the wastewater collection service to continue but results in severe environmental contamination and potential health hazards. This example shows how one service may be provided at nearly 100 % (sewage collection) and if this were the only metric tracked (commonly done after an earthquake), the wastewater system could claim it is resilient from the perspective of providing collection services. However, the transmission subsystem is dictating overall system performance and shows poor resilience relative to the severe and potentially unacceptable impacts on the community and overall environment.

Inundation Protection System Examples

A local community is protected from river flooding by a levee system located along the river banks. The local rainwater runoff within the community is pumped from the drainage pipe network to a local treatment plant then discharged into the river. An earthquake causes severe damage to the levee system, the pump station, and treatment plant. The drainage pipe network has also been significantly damaged but maintains ability to collect and flow water. In many locations the levees have settled below the annual mean river elevation. The earthquake struck at the end of the dry season so fortunately the water level is lower than the mean and no catastrophic water release occurred. However, a relatively significant storm arrived days after the earthquake, before all levees and pump stations could be repaired, and the levee system was overtopped in one location resulting in severe flooding of homes and businesses for many weeks. This inundation protection system may appear to have performed resiliently immediately after the earthquake and even retained water in all but one location throughout its entire length, however since the system functionality was not adequately restored in time to protect against flooding severe impacts to the system and the community result, revealing the low level seismic resilience within the system due to the large number of customers impacted. However, had the system operators known of the potential vulnerabilities and had emergency materials, supplies, contracts, equipment, and other necessary resources on hand to respond in a manner to protect against the overtopping, then the inundation protection system would be shown as resilient to the earthquake strike.

Functionality Versus Operability

Functionality services describe the ability of a system to reliably perform. A highly functional system can achieve its basic purpose (i.e., for water systems provide water delivery, quality, quantity, and fire protection services) prior to completing all infrastructure repairs (e.g., Davis

et al. 2012). Operability describes the cumulative restoration of all services except functionality.

Except for functionality services, the distinction between the other services for each system in Tables 2, 3, and 4 is relatively easy to understand (i.e., for water systems the distinction between water delivery, quantity, quality, and fire protection services is relatively easy to understand). The difference between functionality services and operability for each system is not so inherent and is described in more detail here. Damage imposes constraints that do not allow the system to function with its pre-event performance and reliability in advance of completing all necessary repairs, even when the other services are completely recovered. For example, in a water system after the water delivery, quality, quantity, and fire protection services reach 100 % restoration the system may be fully operational and able to completely service customers (herein, at this state the system is termed operational and has operability) prior to the system being fully functional. The state of complete operability is mostly from the customers' perspective of having all services restored, but the system may not operate or function as it did prior to the extreme event. Full functionality services are not recovered until the constraints imposed by the event (e.g., component damages) have been removed or resolved by completing repairs, possible new construction, and/or operational modifications. A complete functionality recovery returns all services to their pre-event performance, reliability, and redundancy level, at which time the system can operate or function as it did prior to the event. Thus, the functionality services are the last to be fully restored and may be completed after or along with some or all of the other services. In the inundation protection system example provided in the previous section, if the levees were adequately repaired in time to resist all upcoming river flows the system could be considered operable, but not fully functional until all repairs were completed and returned to at least pre-earthquake conditions. Figure 3 shows bounding curves identifying operability using the same serviceability

Resiliency of Water, Wastewater, and Inundation Protection Systems, Fig. 3 Example service restorations showing bounding operability curves (a) water services; (b) wastewater services; (c) inundation protection services

examples of Fig. 1. Operability may be controlled by one or more service categories.

This view of functionality is consistent with that normally considered for resilience modeling (e.g., Bruneau et al. 2003; Cimellaro et al. 2010), with the exception presented herein distinguishing the important difference between the system operability and functionality. For example, in the context of this entry, Cimellaro et al. (2010) define recovery time as the period necessary to restore system functionality to a desired level that can operate or function the same, close to, or better than the original one (which is not achieved until all significant system components are restored to pre-event conditions, i.e., when all significant operations restraints are removed). Bruneau et al. (2003) identifies restoration as the time when the infrastructure is completely repaired. Understanding the difference between system functionality and operability is important for distinguishing the difference in system resilience and the systems' support to community resilience. Operability recovery provides a direct measure of a systems' support to community resilience, and functionality recovery is a measure of water, wastewater, or inundation protection system resilience. Operability recovery is critical for community resilience, and functionality recovery is critical for ensuring the community recovery is complete and sustainable. The difference in operability and functionality restoration and recovery times lies mostly in system redundancy and resourcefulness, which are dimensions of resilience (Bruneau et al. 2003).

As previously described, operability is achieved through a combination of service restorations, but cannot by itself be described as a service. The time it takes to obtain operability status throughout a system can only be viewed as the temporal sum to incrementally restore all the services other than functionality (e.g., wastewater collection, quality, disposal, and reclaimed source for wastewater systems) and therefore serves as a descriptive milestone delineating when customers resume receipt of their accustomed services. Thus, it is important to understand how to assess each service category and its respective characteristics.

Service Equilibrium Shift

Figures 1 and 3 assume the normal pre-earthquake service level (i.e., the horizontal line at 100 %) remains stable during and following the earthquake event. The previous descriptions only indicated the functional services may have a final restoration that may not match the pre-event level for water and wastewater systems (see Fig. 1a, b). However, it is possible for all service categories to have a short-term or long-term stability that does not match the pre-event service levels. This involves a service equilibrium shift (SES) in the net loss or gain in serviceability (a gain is shown for functionality in Fig. 1a, b). In many cases, any potential SES is a function of the system's interaction with the greater community's resilience. A net loss in services may result either from the inability of a damaged system to support the pre-event number of services or the inability of the community as a whole to sustain the number of people and industries, regardless of the systems' ability to support the services. The March 11, 2011, Great East earthquake and tsunami disaster in the Tohoku region of Japan provides numerous examples of this problem. The destroyed communities were not resilient to the tsunami hazard resulting in a permanent decrease in the total number of water, wastewater, and inundation protection services. At some point after an event causing a permanent SES, the curves will need to be re-normalized by the post-event number of service connections to account for the permanent loss in demand.

Figure 4 shows an example water system quantity restoration curve having a temporary 40 % reduction and a permanent 20 % reduction. This may result from an earthquake severely impacting water supply such as ground water wells, aqueducts, or other sources. In this example a 40 % or greater conservation is needed between times t_0 and t_1 , time of earthquake strike and time when temporary SES is removed, respectively. At time t_1 an additional 20 % of water supply is restored, but the community must now adjust to a permanent 20 % loss in water supplies. Restoration curves similar to

Resiliency of Water, Wastewater, and Inundation Protection Systems, Fig. 4 Example quantity service equilibrium shift (SES)

Fig. 4 may be created for any of the service categories presented in Tables 2, 3, and 4 and may even show an increase in services as indicated for functionality in Fig. 1a, b. The SES characteristic shown in Fig. 4 as a permanent loss is not inherent to all systems, but may result from certain extreme events.

The examples in Fig. 1 show all categories having a common trend of initial service declination then an increase in service restorations until completed. In real post-earthquake situations, the ability to maintain a continuous upward trend, once initiated, is highly dependent upon how the restoration activities are managed. Managers in charge of restoration should make decisions to target a continued upward trend in restoration after controls have been established to stop the downward trend. It is possible to have a drop in services within the upward trend. An actual case where this has occurred is presented in the Case Study section later in this entry. Repeated serviceability drops (even just one) can have significant ripple effects and potentially serious impacts to the community. The inundation protection system example in the [System Services and Seismic Resilience](#) section has a severe reduction in flood defense services a few days after the earthquake.

Quantifying Post-earthquake System Services

The service restoration calculation methodology is as follows: (1) identify the area (s) where services are not being met, (2) count the number of services (or people, businesses, etc.) in each area, and (3) calculate the ratio for number of post-earthquake services to pre-earthquake services for each category in Tables 2, 3, and 4. The water, wastewater, and inundation protection service restoration curves are plots of this quantification over time. For post-event restoration estimates, the calculation for all services except functionality is relatively independent of system layout and operations, whereas an assessment for an earthquake scenario may require an understanding of system layout and some hydraulic analysis. Functionality services, however, cannot be estimated in any case without a full understanding of systemic capabilities. For this reason the remainder of this section describes quantification of post-earthquake functionality.

Functionality characterizes the ability of a system to operate in a damaged state and provide services in a manner customers are used to receiving. Damage imposes operational

constraints, and the system cannot function at its pre-earthquake performance and reliability in advance of removing these constraints even when all the other system services (i.e., Tables 2, 3, and 4) are completely recovered. Tables 2, 3, and 4 identify performance and reliability as critical service aspects captured by functionality.

Functionality services S_f can be estimated from

$$S_f = \frac{m}{N} = \frac{1}{N} \sum_i^{\eta} m_i \frac{F_P F_R}{1 + R} \Big|_{\text{equiv}} = \frac{1}{N} \sum_i^{\eta} m_i E_i \quad (1)$$

where m is the weighted average number of services providing functionality, m_i is the number of services in service area A_i , η is the total number of service areas to be evaluated, F_P is the performance factor applied to each line or node to quantify its operational or hydraulic performance capability, F_R is the reliability factor applied to each line or node to quantify its seismic or structural reliability, and R is the redundancy factor. The number of services m_i may be evaluated in alternative forms using total service connections, population, land area, etc. $E_i = F_P F_R / (1 + R) \Big|_{\text{equiv}}$ is the equivalent performance-reliability/redundancy (PRR) calculated for all complete flow paths to or from A_i .

Equation 1 evaluates the water, wastewater, and inundation protection systems as networks of lines and nodes. Lines are conduits carrying water (e.g., channels, pipes, tunnels, etc.). Nodes are points of line initiation, intersection, or ending and may represent different types of water facilities (e.g., reservoir, pump station, treatment plant, etc.) or the connection of one or more lines. The term component is used herein to describe lines and nodes in a general sense.

$F_P \geq 0$ and is defined as the ability of a component to operate or provide flow during and following an earthquake in relation to the components' pre-earthquake performance. For components operating after an earthquake but not with the pre-earthquake performance, then

$0 < F_P < 1$. $F_P = 0$ for each component having a complete loss in operational ability because damage, either to that component or another upstream component, prevents the ability to operate. $F_P = 1$ for operable components having the ability perform at pre-earthquake levels, even if they are not utilized (i.e., water is available and component can perform at full capacity, but component may remain isolated from utilization). From this F_P for each component within each subsystem can be quantified as the ratio of pre- to post-earthquake performance capability. Thus, F_P is quantified by a variety of metrics including flow rate for conduits; volumes for supply and storage; flow rate and pressure for pumping; turbidity, taste, bacteria, etc., for water quality; and so on. Additionally, flow and volume change relative to customer demand/protection and therefore F_P can vary depending on time of day and year. As a result, S_f may change depending on the metric used to evaluate F_P (e.g., for flow, average daily, peak daily, average annual, or other demand values may be used). Therefore, it is important to clearly define and report the metrics used in the evaluations.

$F_R \geq 0$ and is defined as the probability that a component will function during and following an earthquake in relation to the components' pre-earthquake reliability. For components functioning after an earthquake but not with the pre-earthquake capability, then $0 < F_R < 1$ (components are damaged and weakened but operable to some degree). $F_R = 1$ for operable components having the ability to function at pre-earthquake reliability levels (essentially undamaged). $F_R = 0$ for each component having a complete loss in reliability (i.e., damage has removed all ability to operate); in such cases $F_P = F_R = 0$. F_P is dependent upon F_R when damage removes total operability; however, F_P and F_R are not necessarily correlated when $F_R \neq 0$. For example, a pipe can be damaged with $0 < F_R < 1$ while $F_P = 1$; this means the pipe is still fully operable but with less reliability than its pre-earthquake state. An undamaged storage tank with $F_R = 1$ may not be operable ($F_P = 0$)

because it cannot receive water to store due to other system damages.

Each redundancy is assigned a coefficient R_j :

$$R_j = \frac{\sum Q_j}{Q_j} - 1; \quad Q_j \leq \bar{Q}_i; \quad \sum R_j \geq 0 \quad (2)$$

where Q_j is the flow capacity through route or path j and $\bar{Q}_i$ is the total pre-earthquake flow demand to or from A_i or a point p_i .

The equivalent PRR for route k made up of j components in series is

$$E_k = \prod \frac{F_{P_j} F_{R_j}}{1 + R_k} \quad (3)$$

The equivalent PRR for l routes in parallel is calculated from

$$E_k = \sum_r \frac{\prod_j F_{P_{jl}} F_{R_{jl}}}{1 + R_l} \quad (4)$$

where Σ and Π are the operators for summation and product, respectively. $F_{P_{jl}}$ and $F_{R_{jl}}$ are the factors for the j th component on route l . Equations 3 and 4 are used to assemble the equivalent PRR for all paths to a service area. Davis (2014a) provides an example on how to apply the above relationships.

Case Study of Los Angeles Water System Restoration

To further illustrate service restorations, results of an actual water system earthquake performance and post-event service restorations are presented for Los Angeles following the 1994 Northridge earthquake. This case identifies the importance for documenting post-earthquake restorations for all service categories. Case studies quantifying system performance capabilities improve our currently limited knowledge on the complex interactions between (a) the service categories and (b) service restoration and community resilience.

On January 17, 1994, a moment magnitude 6.7 earthquake struck the northern area of Los Angeles and caused significant damages to the Los Angeles Department of Water and Power (LADWP) infrastructure. In summary, there were 14 repairs made to the raw water supply conduits, more than 60 repairs to treated water transmission pipes, 1,013 repairs to distribution pipe, over 200 service connection repairs, 7 reservoirs were damaged, half the treatment plant was temporarily removed from service, and some other incidental damages. Total water system repair costs reached \$41 million. Davis et al. (2012) describes the damage, water outage areas, post-earthquake system performance, and service restorations, which are summarized here.

Figure 5 shows the water service restoration curves for the LADWP following the 1994 Northridge earthquake. As seen in Fig. 5 the water delivery service dropped to about 78 % shortly after the earthquake due to water leaking from broken pipes. The LADWP's ability to contain the impacted area and initiate restorations rapidly allowed the water delivery services to increase soon after the earthquake. The quantity and fire protection services dropped to a low of about 72 % on January 17, 1994. The quality service dropped immediately to zero because a water purification notice was issued across the entire city within 3 h after the earthquake. As shown in Fig. 5, the water delivery service was restored to 100 % at about 7 days, quantity and fire services at about 8.5–9 days, and quality service at 12 days after the earthquake. The rapid increase in quality service within 1 day after the earthquake resulted from recognition that much of the system was not damaged and water quality was maintained in the undamaged areas. The drop in quality service for about 3 days, around 2 days after the earthquake, resulted from the realization that a portion of the pipe network where the water purification notice had previously been removed suffered greater damage than initially recognized; upon recognition the notice was reinstated. The remainder of quality restoration was primarily due to

Resiliency of Water, Wastewater, and Inundation Protection Systems, Fig. 5 Los Angeles water system service restorations following the 1994 Northridge earthquake

Resiliency of Water, Wastewater, and Inundation Protection Systems, Fig. 6 Los Angeles water system functionality service restorations following the 1994 Northridge earthquake

disinfecting the broken pipe network after sufficient repairs were completed to restore flows and pressures. Figure 5 shows the operability state was completely governed by water quality restorations.

The Los Angeles water system has a high level of supply and transmission redundancy which was utilized to provide continued services through the non-damaged portions of the system. Figure 6 shows the entire functionality service restoration, which is calculated using the

methodology described in the previous section for the supply, treatment, transmission, and distribution subsystems. The entire functionality restoration can be viewed at different scales for the first 15 days in Fig. 5, the entire duration in Fig. 6, and the first 100 days are blown up in the inset of Fig. 6. The functionality services initially dropped to about 34 % and began to improve soon thereafter as restorations were undertaken to the supply and transmission subsystems. As seen in Fig. 5, functionality service

does not initially track with operability or any of the other service categories; this is because damage to the supply reduced reliability to a much greater area than the main damage zone. The functionality service rapidly increased to about 60 % once critical repairs to major supply and transmission lines were completed a few days after the earthquake, followed by a relatively linear increase to 70 % for about the next 2 weeks. At 30 days after the earthquake functionality services reached 82 %, after which, as shown in Fig. 6, there were long periods between relatively small incremental service improvements until the functionality returned to normal at about 9 years after the earthquake. Several improvements were made to the system as a direct result of knowledge gained and repairs made following the 1994 earthquake; these were initiated at about 6 years and increased reliability above the pre-earthquake levels after about 9 years. All improvements were completed after 18 years resulting in a positive SES, thereby increasing the post-earthquake functionality to 105 %. The water delivery, quantity, fire protection, quality, and functionality curves are calculated from recorded data and show how the service categories in Table 2 are applied to characterize post-earthquake system performance in an actual operating system severely impacted by an earthquake.

Summary

Descriptions of normally provided water, wastewater, and inundation protection service performance categories have been presented in relation to their importance to post-earthquake system restorations. A clear distinction is made herein between functionality service restoration and system operability (restoration of the other service categories for each system) and their respective relations to (a) water, wastewater, and inundation protection system resilience and (b) community resilience. Methodologies useful for estimating and tracing the service restorations over time have been presented. A case study on service restorations for the Los Angeles

Water System applied these methodologies and showed how the service categories are applicable to actual systems that experience earthquake damage. The relationship between water, wastewater, and inundation protection system service restorations and seismic resilience was illustrated; system resilience cannot be fully described independent of community resilience.

Introduction

Resourcing for post-disaster reconstruction is a complex and dynamic process that goes beyond the provision of building materials, labor, and plant. The interplay between economic recovery following earthquake disasters and time compression often poses resourcing issues, including a lack of desired skills and qualifications, the competition for limited resources, demand surge, and the management of migrant labor. Resourcing post-disaster reconstruction projects tends to be considered a procurement responsibility for construction professionals rather than an integral issue in disaster recovery. However, the outcomes largely depend on the way and extent to which the stakeholders leverage their influence and value into resourcing. Reconstruction following a major disaster poses a particularly challenging problem of planning recovery programs in a way that it can respond to both short-term and long-term resource availability.

The United Nations International Strategy for Disaster Reduction UNISDR defines a disaster as, “A serious disruption of the functioning of a community or a society causing widespread

human, material, economic, or environmental losses which exceed the ability of the affected community or society to cope using its own resources.” Disasters often lead to a reduction of production capacity but also to an increase in the demand for the reconstruction sector and goods. Thus, in theory, the reconstruction acts as a stimulus on the economy.

It is usually the inadequacy of resources and capacities to rebuild that makes the implementation of reconstruction programs particularly difficult. Following a major disaster, most local production facilities and supply systems in manufacturing industries are likely to be damaged, and the construction market tends to be in disorder and contested. Disruption of transportation and energy supply systems can exacerbate supply problems. In addition, preexisting problems within the construction industry can exacerbate the difficulty in procuring building expertise and materials. Resourcing issues thus arise more frequently following a large disaster due to the restructuring of economic activities as a consequence either of the disaster itself or of the reconstruction.

Characteristics of a Post-disaster Resource Market

In the immediate aftermath of a disaster, the assessment of resource requirements tends to be undertaken in parallel with damage assessment. In order to combat the shortage of resources for the rebuild, it becomes imperative for public agencies to develop quantitative models for projecting demand of various resources over the recovery timeframe. Based on an extensive mapping exercise, decisions need to be made quickly on what resources are needed, where the shortages are, what the sources are, and how to ensure their availability in a timely manner. Sometimes national- or local-level policies and plans may exist to guide the development of materials and workforce capacity to meet the reconstruction task, but all these are subject to change as more precise damage information becomes available.

Post-disaster reconstruction is affected by the interplay between time compression and natural

disaster economics. Time compression requires an unusual pace of capital expenditures and reconstruction. Under the pressure of limited time, the need to replace lost homes, infrastructure, and commercial properties generates a significant demand surge for materials and construction workers. In the short term, issues such as material and skill shortages for reconstruction invariably alter the landscape of resource demand and supply. It is therefore common to find environmentally related resource consents are fast tracked for the quarry industry to increase their production capacity. It is also common to find the training and education programs are consolidated for those who are eager to enter the building industry, catching the reconstruction boom.

Unfortunately, the resource shortages and their effects on reconstruction tend to be considered to be a short-term issue. The fact that resource demand is very evenly distributed across different stages and different sectors of reconstruction tends to be overlooked by policy makers. In some cases, the repercussions of a lack of resources for reconstruction can be felt over a long period. For example, 3 years after the 2004 Indian Ocean tsunami, post-disaster housing reconstruction in Indonesia faced:

- A large unused inventory of imported construction products such as windows, doors, and roofs as a result of changes to design
- Suspended progress on house rebuilding due to overstretched budgets (Fig. 1, photo: Chang-Richards)
- Many newly built houses that had to be demolished as a result of the poor quality of construction materials and workmanship
- A multitude of tsunami-affected beneficiaries who were still living in temporary shelters awaiting permanent homes promised by donors

There are several factors which, through their interaction and combined effects, inflate resource demand in post-disaster reconstruction. These include revised building codes and standards, regulatory requirements, construction innovation, environmental concerns, altered housing culture, and budgetary constraints. Research in

Resourcing Issues Following Earthquake Disaster, Fig. 1 Suspended progress on construction of a post-tsunami house in Aceh, Indonesia

this area demonstrates that a dynamic resourcing perspective and approach is a key requirement for dealing with these uncertainties and complexities inherent in the reconstruction process.

Resourcing Approaches for Post-disaster Reconstruction

Resourcing broadly encompasses a wide range of activities that have a bearing on resource management for post-disaster reconstruction projects, embracing pre-event resource planning and preparedness, resource procurement, resource delivery, and the development of resource alternatives. Conventional measures have been employed in past reconstruction practice to address resourcing problems, such as new investment in production and importing resources from outside affected areas. These measures tend to be ad hoc and seem to be unable to perform well to alleviate resource shortages in the long run. In addition, the absence of pre-event planning and preparedness, the inadequacy of efficient and flexible institutional arrangements, and the lack of proactive engagement of the construction industry in disaster management all contribute to undermining resourcing performance in a post-disaster environment.

The empirical research conducted by Chang et al. (2010) recognized that, in order to arrive at

a resilient and sustainable built environment after a disaster, resourcing efforts should be made around four components:

- A resourcing facilitator: legislation and policy
- A resourcing implementer: the construction industry
- A resourcing platform: the construction market
- Resourcing access: the transportation system

The dynamic resourcing process for post-disaster reconstruction reveals that resource availability depends on how relevant stakeholders address resource constraints including resource cost, quality, quantity, environmental concerns, and cultural acceptance.

The type of resourcing approach can be defined in terms of the way and extent to which the stakeholders leverage their influence and value into resourcing activities. Four main resourcing approaches have been widely applied in past disaster reconstruction practice.

1. *Government-driven resourcing approach*: post-disaster reconstruction resource availability is mainly driven by governmental agencies and other authorities.
2. *Donor-driven resourcing approach*: donors play a dominant role in resourcing efforts for a post-disaster reconstruction project.
3. *Market-driven resourcing approach*: the instruments, forces, and rules in the construction market have a major influence on resource availability for post-disaster reconstruction.
4. *Owner-driven approach*: house owners are responsible for rebuilding their own houses through self-maintenance with limited external financial, technical, and material assistance.

In 1974, Cyclone Tracy destroyed the city of Darwin in North Australia. The post-Darwin cyclone reconstruction adopted a government-oriented resourcing approach. The Australia government initiated restrictions on building projects in order to control resource prices. However, post-cyclone inflation was about 75 %, and this

impact even extended to Townsville in the state of Queensland (Walker and Minor 1979).

In contrast, the 1989 Newcastle earthquake in Australia was different because a more market-driven resourcing approach was allowed and the government only controlled building standards. The post-earthquake inflation in Newcastle was about 20 % (Shephard et al. 1997). This inflation was largely due to the differing view of clients' engineers and insurers on what remedial work was required (Walker 1995).

The 1994 Northridge earthquake in the United States shows that resource availability can be further enhanced by government commitment to improve its environment and to help facilitate the procurement and development of resources. Wu and Lindell (2004) highlighted that having a pre-impact recovery plan in Los Angeles, with resource availability as one of its targets, facilitated housing reconstruction and allowed local officials to manage the reconstruction process more effectively. Other cases, such as recent events in New Zealand and Japan, show that by investing in construction apprenticeship training and sectoral programs, the government enhanced the market players' capacity to cope with large-scale disaster reconstruction demand.

Donor-driven resourcing occurs when nongovernment organizations (NGOs) or other designated organizations are tasked with housing rebuilding projects for beneficiaries, often in underdeveloped countries where the indigenous resources and capability are unlikely to cope with large-scale disasters.

In comparison with donor-driven resourcing, the owner-driven/community-driven approach is empowering and participatory and thus was popular in post-tsunami reconstruction in Indonesia among NGOs, such as the United Nations High Commissioner for Refugees (UNHCR), the United Nations Children's Fund (UNICEF), and World Vision, which consider community redevelopment and participation as being among their main objectives.

The UNDP, in conjunction with UN-HABITAT, designed the Aceh Nias Settlements Support Program (ANSSP). This program promoted self-construction with funding support

from aid agencies in forms of cash grant or transfer. Aid agencies also provided technical assistance with regard to material selection and procurement in some affected rural areas in Aceh. UN-HABITAT also introduced “People’s Process” in Aceh to allow a fully empowering community-organized reconstruction to make the best use of local resources and capabilities.

The four models work holistically and are essentially transferable under a specific reconstruction circumstance. For example, the government may control the supply of cement, which is purchased by a contractor or an NGO for construction work, with or alongside a community constructing its own houses. Hence, there is a continual shifting between these models in post-disaster resourcing for reconstruction. It is when this balance is distorted that resourcing issues appear. For example, there were cases in which local governments restricted the supply of cement in Sri Lanka and the supply of timber in Simeulue, Indonesia, after the 2004 Indian Ocean tsunami and the supply of roofing in Pakistan after the 2005 Kashmir earthquake. International NGOs imported these resources from outside the affected areas where local contractors and communities were unable to cope with resource shortages, and longer-term resourcing problems appeared.

The four types of resourcing approaches can overlap or combine in the same recovery operation. Government-driven resourcing does not necessarily imply that the government gets involved in actual resource procurement for housing reconstruction projects but that the authorities retain full control over the resource provision and supply process. The success of market-oriented and donor-led resourcing in post-disaster housing reconstruction also requires continual government participation and lies largely in the way and extent to which the authorities provide facilitation.

Resourcing Issues Following a Major Disaster

Resourcing for post-disaster reconstruction is often construed as a procurement responsibility

for construction professionals rather than an integral issue in disaster recovery. This approach underestimates the complexity of the real economic challenge that disasters pose to communities. In reality, reconstruction following a major disaster must confront important resourcing issues such as a lack of desired skills and qualifications, the competition for limited resources, demand surge, and the management of migrant labor.

The tendency in post-disaster situations is often to revise building codes and standards in order to enhance the resilience of structures to future disasters. However, this regulatory change induces the changes to the requirement of materials, skills, tools, and techniques in new construction. New materials and skills may not be available in the time of reconstruction as it requires a considerable time for manufacturers to undertake the research and development, to test and release these new materials onto the market. The additional costs of the new construction requirements are often not well reflected in the regulatory impact statement due to uncertainties and the real-time nature of disaster events.

Therefore, governments tend to set their recovery policy on the assumption that the prices of building materials will rise rapidly when the rebuild ramps up in earnest but will gradually fall again as the peak of reconstruction passes the spikes in construction demand. Agencies are inclined to respond to the anticipated resource shortages during the reconstruction boom time or simply leave it to the market. Research in this area has shown that when the resourcing issue is not handled well, it will lead to a secondary economic disaster manifested by inflationary chaos, “Dutch disease” or demand surge. “Dutch disease” is named after the experience in the Netherlands of deindustrialization in the wake of large inflows of export revenues from North Sea Oil in the late 1970s. It is known as the negative impact on the non-booming sectors due to the simultaneous and competing demand for inputs between booming sectors and non-booming sectors. These adverse market responses can worsen local economies, causing time and cost effects on disaster reconstruction projects.

More resource challenges may appear in countries where the local natural resources are already severely deprived prior to a disaster. “Business as usual” projects, capital works, and development projects may also play a part, absorbing wider market space from recovery projects. The impacts of resource shortages on recovery are more profound when time is tight, and the government is under political pressures. In post-tsunami reconstruction in Indonesia, for instance, some house owners or aid agencies turned to available inferior resources or sought to import materials from outside the region with lengthy lead times. As could be expected, without appropriate site supervision and quality control in place, a variety of construction defects and failures associated with poor building materials and workmanship occurred (Fig. 2, Photo: Chang-Richards).

Implications of Demand Surge

Demand surge is a prominent feature associated with large-scale natural disasters, one which entails higher repair or rebuild costs resulting from higher labor wages and material prices following a large- versus small-scale disaster. Increased repair and rebuild costs after large-scale disasters have fallen into a broad range between 20 % and 250 %. For example, after the 1994 Northridge earthquake (US), insurers observed a 20 % increase in the costs to settle claims (Kuzak and Larsen 2005, p. 113). The Cyclone Larry (Australia) saw an increase of 50 % in reconstruction costs (Australian Securities and Investments Commission 2007). Most needed materials brick, aggregate, and cement had costs increase by 127 %, 125 %, and 30 % during the first 6 months of China’s Wenchuan earthquake reconstruction (Chang et al. 2012). Increases of 200–250 % in the costs of construction materials were observed in tsunami-affected Aceh of Indonesia 2 years after the tsunami (Steinberg 2007).

A number of project actors are often confronted with the problem of escalated costs for indemnifying properties exposed to disasters.

Resourcing Issues Following Earthquake Disaster, Fig. 2 Poor building materials and workmanship in a newly rebuilt house in Aceh, Indonesia

These actors might include agencies of national and regional governments, local government, international agencies, nongovernmental organizations, financial institutions, insurers, reinsurers, and the affected populations. In the last few decades, anticipating demand surge in the event of a natural disaster has been of a primary interest to many insurance and reinsurance companies. Common demand surge models include products from AIR Worldwide, EQECAT, and RMS (Risk Management Solutions).

Although the circumstances contributing to increased reconstruction costs are disaster-specific, there are common explanations for demand surge across events. Research in this area suggests the following factors: the total amount of repair work; the costs of reconstruction materials, labor, and equipment; reconstruction timing; construction contractor fees; general economic conditions; insurance claims handling; and decisions of an insurance company (Olsen and Porter 2013). Among these factors, the increased cost of reconstruction labor and materials is the most common explanation for demand surge.

A more obvious implication of demand surge is likely to be a marked increase in salaries as organizations compete for a decreasing cohort of able workers. Simultaneously, those experienced professionals are likely to be poached by competitor organizations who may offer better fringe benefits and remuneration packages. Spiraling employment linked to tight labor market

conditions ultimately impacts upon the cost of construction projects. The reinforcing effect of interplay between competition and demand surge may persist in the longer term even after the demand surge has passed as evidenced in Aceh of Indonesia following the 2004 Indian Ocean tsunami.

As a result of demand surge, many post-disaster housing projects may suffer from funding shortfalls, further strains on local government expenditure, revised scope of projects, and even project failure. This can be an insurmountable problem and, at worst, result in a huge waste of resources when projects are left half constructed. Some aid agencies in Indonesia, for example, found themselves having to compromise their housing number commitments to local government and beneficiaries, while others experienced significant reconstruction delays and project failures.

The amplification of demand surge impacts comes when there are other developments elsewhere that may pose increased and competing demand and place additional pressure on both human and material resources. For instance, current and future investment in Queensland, Australia's mineral and energy projects are anticipated to have a substantial impact on the demand for labor resources, while the reconstruction and recovery of communities from 2010 to 2011 Queensland floods and cyclones is underway. Whether for reputational advantage, market efficiency, or political reasons, minimizing the impacts of demand surge on the economy has moved from being a concern of local economists to a major component of post-disaster reconstruction strategy, labor market, and economic recovery programs.

Management of Migrant Labor

Those resourcing methods which are based on neoclassical economics and deal mostly with the larger economy tend to consider resource availability as a consequential result of market processes. An organizational perspective is often missing which explains both internal resourcing

dynamics and the linkages between construction organizations and the wider recovery environment. As part of a business initiative, construction organizations may try to upskill workers or import skills from elsewhere outside the disaster zone. The difficulty here is that even when people are trained with construction and engineering skills, only rarely can they be readily competent for the job. Organizations often face a dilemma where they are committed to using local resources but still need to look for expertise from outside to fill vacancies, especially those high-value jobs.

At an organizational level, resourcing skills for reconstruction projects and programs come from a variety of sources. Research in this area demonstrates that sourcing construction professionals from outside for their rebuild projects often have positive results from organizations' perspectives in terms of their confidence in work quality, their economic position, and business performance. In order to attract and retain those nonlocal workers, organizations may have to offer appealing remuneration packages, which may vary from organization to organization. For example, assistance with relocation by an organization in Christchurch, New Zealand, may include the facilitation of immigration, providing temporary accommodation, schooling arrangement for young children, and social networking and employment assistance for the worker's spouse (see Table 1).

In some situations, the capacity of the local construction sector is insufficient for large-scale reconstruction and a large number of workers from outside are needed. There are often challenges associated with managing migrant labor within a local context such as culture, housing, lifestyle, and work ethos. For instance, it was difficult for migrant workers from Java to adapt to a completely different lifestyle and livelihood customs in Aceh after the Indian Ocean tsunami. There was a high rate of worker turnover between projects and organizations. Organizations found it difficult to secure these skills unless constantly increasing labor wages. Influx of labor may also pose a significant challenge to an already strained housing market. A housing crisis may result when

Resourcing Issues Following Earthquake Disaster, Table 1 Demographic features of migrant workers for rebuild in Christchurch

	Engineers	Building control professionals
Origin	Earthquake-prone countries – the USA, Italy, Spain, Chile	Europe, Australia, the USA
Age cohort	25–35	30–50
Work experience	New graduates or more than 2 years experience	At least 5–10 years plus experience

Source: Chang-Richards et al. 2012

there is a lack of reasonable alternative housing available for disaster victims, and/or construction workers compete with locals for limited housing stock and putting those lower-income people at risk of displacement.

In addition, a lack of accommodation for construction workers may become a major constraint to the rebuilding process. The construction sector may experience difficulties sourcing temporary accommodation for out-of-town workers in suitable and affordable solutions. Demand for housing from construction workers is likely to compound the shortage of houses available to residents displaced by the earthquakes. Competing demand for temporary accommodation is likely to contribute to post-disaster demand surge and thus inflation region wide. For example, following the 22 February 2010 earthquake in Christchurch, New Zealand, the rental market failed to meet the needs of inbound construction workers seeking affordable accommodation. Some areas such as “Inner North” and “North West” recorded above-average rent increases of 39 % and 32 %, respectively (MBIE 2013).

In general, the decision to develop site accommodation for workers is based on factors such as impacts of workers’ accommodation on communities, quality of housing stock, financial viability of investment, scale of demand, and accessibility to land and infrastructure. In low-income nations, local government and construction organizations play a large role in providing on-site temporary accommodation for workers. This may be

assisted by nongovernment organizations. However, gaining consents from local authorities for developing such an accommodation project on public or private land might be a particularly daunting task in high-income countries. Local government needs to revise the housing and planning policies to allow either temporary or semi-permanent structures to be built. It also requires the revision of zoning and building code controls to facilitate and encourage the development of different housing models.

Summary

Resourcing for post-disaster reconstruction is a complex and dynamic process in which resource demand is unevenly distributed across different stages and different sectors of rebuild. Varying the resourcing approach involves leverage of stakeholders’ influence and market forces to a varied degree. This implies facilitating organizational responsibility over sourcing and managing resources to meet reconstruction tasks. It also implies facilitating collective responsibility among project actors over resource needs to mitigate the resource risk for the rebuild.

Resourcing bears on a variety of issues inherent in the post-disaster reconstruction context. This process requires a systemic and dynamic support on recovery planning systems, industry capacity, regulatory framework, and economic issues at both project and organizational levels. Research has shown that following a large-scale disaster, resource risks will exist but can be managed. By linking resourcing with broader plans for sustainable and equitable post-disaster reconstruction, more fundamental actions both pre- and post-disaster can be taken to reduce socially and physically produced resource shortages.

Response Spectrum Analysis of Structures Subjected to Seismic Actions

Michalis Fragiadakis

School of Civil Engineering, Laboratory for Earthquake Engineering, National Technical University of Athens (N.T.U.A.), Athens, Greece

Synonyms

Lateral force method; Modal analysis; Modal response spectrum analysis; Modal superposition; Response spectrum; Seismic performance assessment

Introduction

Response spectrum analysis (RSA) is a method widely used for the design of buildings. Conceptually the method is a simplification of modal analysis, i.e., response history (or time history) analysis (RHA) using modal decomposition, that benefits from the properties of the response spectrum concept. The purpose of the method is to provide quick estimates of the peak response without the need to carry out response history analysis. This is very important because response spectrum analysis (RSA) is based on a series of quick and simple calculations, while time history analysis requires the solution of the differential equation of motion over time. Despite its approximate nature, the method is very useful since it allows the use of response spectrum, a very convenient way to describe seismic hazard.

RSA is very appealing to practicing engineers because seismic loading is defined by means of a response spectrum. All design codes worldwide define seismic input (or hazard) by means of a code-compliant, typically smooth, response spectrum that can be easily adjusted according to the site seismic hazard. Such spectra are able to implicitly take into consideration the fact that structures are designed to resist seismic actions

by deforming inelastically. Two variations of RSA are offered in almost every seismic design code. Following the notation of Eurocode 8 (EC8 2004), these variations are the “lateral force method” and the “modal response spectrum analysis.” This entry discusses the underlying concepts of both methods in a comprehensive manner. The interested reader is also advised to consult the classic textbooks of Chopra (2000) and Clough and Penzien (1975).

Modal Analysis

Before proceeding to the discussion of response spectrum analysis, it is essential to have a good understanding of modal analysis, also known as modal superposition method. Modal analysis aims at transforming a fully coupled problem of N degrees of freedom to N uncoupled single-degree-of-freedom (SDOF) problems that can be solved individually, and, in the end, the individual solutions can be superimposed to obtain the solution of the initially coupled problem. The advantage is that simpler methods, including closed-form methods, can be used to solve the single-degree-of-freedom problem. From a computing standpoint, the number of operations required is substantially reduced when modal decomposition is preferred (Bathe 1996). A second reason is that only a small number of modes need to be taken into consideration, while the rest can be neglected with a minimum loss of accuracy. This considerably speeds up the whole process, while the number of modes required depends on the type of loading and the structural properties (i.e., stiffness, damping).

The equation of motion of a system with N degrees of freedom is written as

$$\mathbf{m}\mathbf{u} + \mathbf{c}\dot{\mathbf{u}} + \mathbf{k}\mathbf{u} = \mathbf{q}(t) \quad (1)$$

where $\mathbf{m}$, $\mathbf{c}$, and $\mathbf{k}$ are the mass, damping, and stiffness matrices, respectively, while $\ddot{\mathbf{u}}$, $\dot{\mathbf{u}}$, and $\mathbf{u}$ denote the vectors of acceleration, velocity, and displacement and are always functions of time. $\mathbf{q}(t)$ is the vector of applied loads, again defined as function of time. If the dynamic load is

a ground motion history (acceleration time history), then $\mathbf{q}(t)$ is obtained as

$$\mathbf{q}(t) = -\mathbf{m}\boldsymbol{\varsigma}\ddot{u}_g(t) \quad (2)$$

where $\boldsymbol{\varsigma}$ is a vector of order N whose entries are equal to 1 for translational degrees of freedom in the direction of the ground motion and zero otherwise. It is also reminded that the number of modes is N , equal to the number of the degrees of freedom of the system.

By definition, the mode shape vector $\boldsymbol{\Phi}_n$ describes the shape of the n th mode, and the vector of displacements is equal to the sum:

$$\mathbf{u}(t) = \sum_{n=1}^N \boldsymbol{\Phi}_n y_n(t) \quad (3)$$

The coupled equation of motion of Eq. 1 can be uncoupled after substituting $\mathbf{u}(t)$ using Eq. 3 and left-multiplying it with $\boldsymbol{\Phi}^T$. This is achieved with the aid of the orthogonality condition, where the products $\boldsymbol{\Phi}_m^T \mathbf{m} \boldsymbol{\Phi}_n$, $\boldsymbol{\Phi}_m^T \mathbf{c} \boldsymbol{\Phi}_n$ and $\boldsymbol{\Phi}_m^T \mathbf{k} \boldsymbol{\Phi}_n$ are equal to zero if $n \neq m$. The following generalized quantities can be defined when $n = m$:

$$\begin{aligned} M_n &= \boldsymbol{\Phi}_n^T \mathbf{m} \boldsymbol{\Phi}_n \\ C_n &= \boldsymbol{\Phi}_n^T \mathbf{c} \boldsymbol{\Phi}_n \\ K_n &= \boldsymbol{\Phi}_n^T \mathbf{k} \boldsymbol{\Phi}_n \end{aligned} \quad (4)$$

It is also assumed that

$$Q_n(t) = \boldsymbol{\Phi}_n^T \mathbf{q}(t) = -\boldsymbol{\Phi}_n^T \mathbf{m} \boldsymbol{\varsigma} \ddot{u}_g(t). \quad (5)$$

The coupled equation of motion (Eq. 1) is equivalent to the following set of equations:

$$\begin{aligned} M_1 \ddot{y}_1 + C_1 \dot{y}_1 + K_1 y_1 &= Q_1(t) \\ M_2 \ddot{y}_2 + C_2 \dot{y}_2 + K_2 y_2 &= Q_2(t) \\ \dots &\dots \\ M_n \ddot{y}_n + C_n \dot{y}_n + K_n y_n &= Q_n(t) \end{aligned} \quad (6)$$

If we divide by M_n and assume $C_n = 2\zeta_n \omega_n$ and $K_n = M_n \omega_n^2$, the equations are further simplified to

$$\ddot{y}_n + 2\zeta_n \omega_n \dot{y}_n + \omega_n^2 y_n = -\frac{L_n}{M_n} \ddot{u}_g(t) \quad (7)$$

where

$$L_n = \Phi_n^T \mathbf{m} = \sum_{j=1}^N m_{nj} \Phi_{nj} \quad (8)$$

For brevity, only the last equation of Eq. 7 is shown. Equations 6 or 7 are not coupled and therefore can be solved separately to obtain y_n . Equation 7 can be seen as the equation of motion of a SDOF with frequency ω_n subjected to a strong ground motion whose amplitude $\ddot{u}_g(t)$ has been multiplied with L_n/M_n . Otherwise, the solution of Eq. 7 is the solution of a SDOF with frequency ω_n subjected $\ddot{u}_g(t)$ and then multiplied with L_n/M_n .

The ratio L_n/M_n is the participation factor of mode n , which always sums to one and may take both positive and negative values. This quantity depends on how the modes have been normalized and is not equal to the contribution of a mode to a response quantity.

The vector of displacements $\mathbf{u}$ is back-calculated using Eq. 3, and every other response quantity can be subsequently determined once $\mathbf{u}$ is known. For example, the vector of elastic forces will be

$$\begin{aligned} \mathbf{f}(t) &= \mathbf{k}\mathbf{u}(t) = \dots \\ &\dots = \mathbf{k}\Phi_1 y_1(t) + \mathbf{k}\Phi_2 y_2(t) + \dots + \mathbf{k}\Phi_n y_n(t). \end{aligned} \quad (9)$$

For damped systems, the above decoupling is feasible only if the damping matrix $\mathbf{c}$ is orthogonal, otherwise Eq. 6 does not apply. Usually $\mathbf{c}$ is derived as a combination of $\mathbf{k}$ and $\mathbf{m}$, i.e., $\mathbf{c} = \alpha_0 \mathbf{k} + \alpha_1 \mathbf{m}$, where α_0, α_1 are constants. This form of damping is known as Rayleigh damping. Another approach would be to form the damping matrix so that every mode is damped with $C_n = 2\zeta_n \omega_n$. This is achieved with the aid of the formula (Chopra 2000):

$$\mathbf{c} = \mathbf{m} \left(\sum_{n=1}^N \frac{2\zeta_n \omega_n}{M_n} \Phi_n^T \Phi_n \right) \mathbf{m} \quad (10)$$

A fundamental property of modal analysis is that the response can be accurately captured if a, relatively, small number of modes are

considered. Therefore, the question is how many modes should be included in modal analysis. The answer depends on the applied load and on the response parameter examined. For example, more modes are required to accurately capture the base shear than the roof displacement. Since the exact solution is not a priori known, one has to identify the response parameters that are likely to be sensitive to high modes and then decide the number of modes to include. In lieu of the above, some building codes suggest that the number of modes considered should be chosen so that the effective modal masses for the modes taken into account amounts to at least the 90 % of the total mass of the structure. Due to the relationship of the effective modal mass and the base shear, this rule implies that the error in the base shear estimate should be less than 10 %. Moreover, according to Eurocode 8 (EC8 2004), the analysis should include all modes with effective modal masses greater than 5 % of the total.

Example 1: Modal Analysis of a Plane Frame Determine the response of the three-storey plane frame of Fig. 1a when subjected to the Imperial Valley (1979) ground motion record (Fig. 1b). Assume $k = 10,000$ kN/m, $m = 20$ t, and 5 % damping of the critical for every mode.

The mass and the stiffness matrices are obtained as follows:

$$\begin{aligned} \mathbf{k} &= \begin{bmatrix} 1.5k & -k & 0 \\ -k & 2k & -k \\ 0 & -k & k \end{bmatrix} \\ &= \begin{bmatrix} 15,000 & -10,000 & 0 \\ -10,000 & 20,000 & -10,000 \\ 0 & -10,000 & 10,000 \end{bmatrix} \text{ kN/m} \\ \mathbf{m} &= \begin{bmatrix} 2m & 0 & 0 \\ 0 & 2m & 0 \\ 0 & 0 & m \end{bmatrix} = \begin{bmatrix} 40 & 0 & 0 \\ 0 & 40 & 0 \\ 0 & 0 & 20 \end{bmatrix} t. \end{aligned}$$

The eigenvalue problem, $[\mathbf{k} - \mathbf{m}^2] = 0$, is first solved to obtain the eigenmodes (or just “modes”) and the eigenperiods (or just “periods”) of the frame. The eigenperiods are $T = [0.98, 0.31, 0.21]$ s and the mode vector is

Response Spectrum Analysis of Structures Subjected to Seismic Actions, Fig. 1 (a) Plane frame geometry, (b) the Imperial Valley record (15 Oct. 1979)

$$\Phi = [\Phi_1 \Phi_2 \Phi_3] = \begin{bmatrix} 0.69 & -0.95 & 0.38 \\ 0.92 & 0.16 & -0.83 \\ 1.00 & 1.00 & 1.00 \end{bmatrix}$$

The first column gives the first mode and every row corresponds to the modal displacement of the respective storey. The system of Eq. 7 now becomes

$$\begin{aligned} \ddot{y}_1 + 0.64\dot{y}_1 + 40.8y_1 &= -\frac{84.22}{72.62}\ddot{u}_g(t) \\ \ddot{y}_2 + 2.04\dot{y}_2 + 418.2y_2 &= \frac{11.32}{56.90}\ddot{u}_g(t) \\ \ddot{y}_3 + 3.03\dot{y}_3 + 916.0y_3 &= -\frac{2.09}{53.60}\ddot{u}_g(t) \end{aligned}$$

The modal displacements $y_n(t)$ are obtained solving the above equations either using Duhamel's integral or, preferably, numerically using the Newmark's method (Bathe 1996; Chopra 2000). The modal response histories of $y_n(t)$ are shown in Fig. 2. According to the three plots, the modal displacement of the first mode is considerably larger than that of modes two and three (note the different scale of the vertical axes). Moreover, the response histories of higher modes have a more rich frequency content compared to that of lower modes. Figure 3 shows the modal displacements of the third storey, obtained using Eq. 3. The first three plots show the displacement response history of every mode and the fourth plot shows the actual/total displacement of the third storey. Regarding the amplitude and the frequency content, the observations of Fig. 2 still hold.

Moreover, the maxima of every response history occur at different time instants. The figure also implies that we can have a good approximation of the final solution using the first mode only and discarding modes two and three with a minor loss of accuracy.

$$\mathbf{c} = \begin{bmatrix} 71.5068 & -28.9232 & -5.0115 \\ & 75.9453 & -26.4174 \\ \text{sym} & & 40.4784 \end{bmatrix}$$

The final solution of the last plot in the bottom of Fig. 3 has been verified also by solving the equation of motion (Eq. 1) with the aid of Newmark's method. For this purpose, we use Eq. 10 to obtain the damping matrix $\mathbf{c}$ shown above. Direct integration algorithms are usually simpler and their additional computational effort is easily handled by modern computers. Modal analysis may be preferred because it (i) helps decompose the problem and allows drawing qualitative conclusions, (ii) is faster when only the most significant modes are considered, and (iii) is the basis of response spectrum modal analysis.

Response Spectrum

In seismic design problems, in most occasions, it is sufficient to know only the peak values of the response, defined as the maximum of the absolute value of a response quantity $r(t)$ that varies in time (Chopra 2005):

$$r_0 = \max|r(t)| \quad (11)$$

**Response Spectrum
Analysis of Structures
Subjected to Seismic
Actions, Fig. 2** Response
histories of modal
displacements $y_n(t)$ (Eq. 3)

where r_0 is the absolute value of $r(t)$. The response spectrum of a quantity is the plot of the maximum (or peak) value of a response quantity (e.g., displacement, velocity, acceleration) against the full range of interest of the natural vibration period values T_n .

The word spectrum (plural spectra or spectrums) was first used in science within the field of optics to describe the rainbow of colors in visible light when separated using a prism. In other words, “spectrum” implies a broad range of conditions or behaviors grouped and studied together. If a given period value T_n refers to a different SDOF structure, a response spectrum of a quantity by definition provides *the maximum value of the response quantity of interest under a given ground motion for the whole range of*

structures of interest. Therefore, such plots give the maximum response for the whole range (or spectrum) of SDOF structures.

Properties of Response Spectra

Figure 4 shows the response spectra of three recorded ground motion records. Some very interesting observations regarding the properties of the response spectra can be made. All three spectra intersect the vertical axis at an acceleration value equal to the peak ground acceleration, i.e., the maximum acceleration value of the recorded ground motion. This point corresponds to a very rigid SDOF system with period equal to zero. Moreover, the Manjil (1990) and the Assisi-Stallone (1997) ground motions are clearly stronger compared to the Parkfield (1966) record,

Response Spectrum Analysis of Structures Subjected to Seismic Actions, Fig. 3 Response history of the modal displacements of the third storey. The plot in the bottom shows the actual/total response history of the third storey

while the Manjil record has a richer frequency content compared to the Assisi-Stallone record. This stems from the fact that the Manjil record maintains high acceleration values for a wide range of periods, while the Assisi-Stallone spectrum decays quickly. A rich frequency content is also observed in the Parkfield record.

Apart from the observations of the above paragraph, the most important property of a response spectrum is that it provides the maximum acceleration of a single-degree-of-freedom (SDOF) system without the need of performing a dynamic analysis, since all necessary calculations have been already performed in order to draw the spectrum. If $S_a(T_n, \xi)$ is the $\xi\%$ -damped spectral acceleration (ordinate of the acceleration spectrum), the peak deformation of a SDOF with period T_n and damping ξ will be

$$u_{\max} = \omega_n^2 S_a(T_n, \xi) = \left(\frac{T_n}{2\pi}\right)^2 S_a(T_n, \xi) \quad (12)$$

Similarly the peak value of the equivalent static force $f_{s,\max}$ will be

$$\begin{aligned} f_{s,\max} &= k u_{\max} = m S_a(T_n, \xi) \\ &= \frac{S_a(T_n, \xi)}{g} W \end{aligned} \quad (13)$$

where k , m , and W are the stiffness, mass, and weight of the SDOF, respectively.

Integrating the acceleration response history would give the velocity, while the integral of the velocity history provides the displacement response history. This means that acceleration, velocity, and displacement are proportional

Response Spectrum Analysis of Structures Subjected to Seismic Actions,

Fig. 4 Acceleration response spectra for three strong ground motion records

(by a factor ω), except for a phase shift. The phase shift does not influence the maximum response values and therefore the following approximations can be made:

$$\begin{aligned} S_d(T_n, \xi) &= |u_{\max}| \\ S_v(T_n, \xi) &= |\dot{u}_{\max}| \approx \omega S_d(T_n, \xi) = PSV \\ S_d(T_n, \xi) &= |\ddot{u}_{\max}| \approx \omega^2 S_d(T_n, \xi) = \omega PSV = PSA \end{aligned} \quad (14)$$

where PSV and PSA are the pseudospectral velocity and the pseudospectral acceleration, respectively. They are not the exact maxima of velocity and acceleration, but they are very close to the actual values and are usually used in engineering practice.

Design or Code-Compliant Spectra

The response spectra of Fig. 4 refer to the response of all possible SDOF systems of specific ground motion records. On the other hand, a design spectrum recognizes that ground motions at a site may originate from different seismic sources. Therefore, a design spectrum is representative of an ensemble of ground motions and, contrary to the single-record spectra of Fig. 4, its shape is always smooth. Design spectra have been derived from statistical analysis from an ensemble of response spectra and correspond either to a mean or to a mean plus one standard deviation spectrum. They are also known as

“uniform hazard spectra,” since they refer to the same probability of exceedance for the whole range of periods.

A procedure for constructing a design spectrum from peak values of ground acceleration, velocity, and displacement has been presented by Newmark and Hall (1982). The procedure uses the amplification factors of Table 1 and is applied in a logarithmic tripartite log paper where the horizontal axis denotes frequency (Hz). The steps required are quite simple (Fig. 5): (i) first, draw the ground parameters (peak acceleration, velocity, and displacement) each parallel to the corresponding axis. (ii) Then draw lines parallel to them at distances obtained from Table 1. For example, for damping 5 %, the amplification factor of the median acceleration is $3.21 - 0.68 \ln(5) = 2.11$ and 1.65 and 1.39 for the velocity and the displacement spectrum, respectively. (iii) Draw a line connecting the response spectrum at 8 Hz with the ground motion at 33 Hz so that the response of very stiff structures is equal to that of the ground. (iv) Finally, draw another line connecting the response spectrum at 1/10 Hz with the ground motion curve at 1/33 Hz so that the peak response of very flexible systems coincides with the peak ground deformation. Other approaches for creating both elastic and inelastic spectra can be found in the literature.

Design codes give smooth elastic or design spectra. The distinction between elastic and design

Response Spectrum Analysis of Structures Subjected to Seismic Actions, Table 1 Spectral amplification factors for 84-percentile confidence (Newmark and Hall 1982)

Damping (%)	Acceleration	Velocity	Displacement
50 percentile (median)	3.21–0.68 ξ	2.31–0.41 ξ	1.82–0.27 ξ
84 percentile	4.38–1.04 ξ	3.38–0.67 ξ	2.73–0.45 ξ

**Response Spectrum
Analysis of Structures
Subjected to Seismic
Actions,**

Fig. 5 Construction of design spectra according to Newmark and Hall (1982)

spectrum is that the design spectrum is derived from the elastic by dividing the ordinates of the latter by a response modification factor R (according to the terminology used in the USA) or a behavior factor called q in the European practice. Some codes, such as Eurocode 8 (European Committee for Standardization 2004), anchor the spectrum to the peak ground acceleration, but

this is not always the case. In seismic codes that do not specify explicitly the PGA value, it can be inferred either from the acceleration value at period equal to zero or by dividing the flat segment of the spectrum (plateau) with the acceleration amplification factors of Table 1.

The Eurocode 8 elastic spectrum is given by the expression below and is plotted in Fig. 6:

$$S_a(T, \xi) = \begin{cases} \alpha_g S [1 + (\eta 2.5 - 1)(T/T_B)] & , \text{ if } 0 \leq T \leq T_B \\ \alpha_g S \eta 2.5 & , \text{ if } T_B \leq T \leq T_C \\ \alpha_g S \eta 2.5 (T_C/T) & , \text{ if } T_C \leq T \leq T_D \\ \alpha_g S \eta 2.5 (T_C T_D/T^2) & , \text{ if } T_D \leq T \leq 4\text{sec} \end{cases} \quad (15)$$

Response Spectrum Analysis of Structures Subjected to Seismic Actions, Fig. 6

The elastic design spectrum of European Committee for Standardisation (2004)

where S is the soil factor, and T_B , T_C , and T_D are period values that change the shape of spectrum according to the soil conditions. Eurocode 8 recommends the above spectrum for earthquakes of magnitude above 5.5, while another expression is recommended for smaller earthquakes. η is the damping correction factor equal to 1 when $\xi = 5\%$ (typical for reinforced concrete structures) and obtained as

$$\eta = \sqrt{10/(5 + \xi)} \geq 0.55 \quad (16)$$

α_g is the design acceleration which is equal to the importance factor γ_I times the design peak ground acceleration (PGA). Figure 6 shows two response spectra obtained with the formula of EC8 (Eq. 15). The spectrum with the solid line refers to ground type A ($S = 1.2$, $T_B = 0.15$, $T_C = 0.5$, $T_D = 2.0$) and will be used for the design of a reinforced concrete structure ($\xi = 5\%$). The importance factor (γ_I) is considered equal to 1.0 and the design PGA is 0.40 g. The spectrum with the dashed line refers to ground type B ($S = 1.35$, $T_B = 0.2$, $T_C = 0.8$, $T_D = 2.0$), PGA equal to 0.30 g, and $\gamma_I = 1.0$. Note that both spectra intercept the vertical axis at a value equal to $a_g S$, while the horizontal plateau (for $\xi = 5\%$) is at $a_g S 2.5$. 2.5 is the

acceleration spectral amplification factor approximately equal to that given by the expression of Table 1. Both PGAs adopted for the site under consideration have a 10 % probability of being exceeded in 50 years (return period $T_m = 475$ years), and therefore the seismic hazard of both response spectra is uniform and equal to a 10 % probability of being exceeded in 50 years.

Response Spectrum Modal Analysis

Peak Modal Responses

Modal analysis provides the entire response history for a given ground motion record. For design purposes, its application requires a design ground motion record that is representative of the seismic hazard at the site. The use of such records is rare and requires special skills to select them. Hence, in engineering practice, the seismic hazard is defined preferably with the aid of regional response spectra as discussed the “[Properties of Response Spectra](#)” section.

Moreover, for design purposes, we usually use the maximum value of a response parameter and not the entire response history. Since every mode can be treated as an independent SDOF system, the maximum response values of a mode can be

easily obtained from the corresponding response spectrum (Eqs. 12 and 13).

If $S_d(T_n, \xi)$, $S_v(T_n, \xi)$, and $S_a(T_n, \xi)$ denote the spectral displacement, velocity and acceleration, respectively, the maximum modal displacements are obtained from a response spectrum as

$$y_{n,\max} = \frac{L_n}{M_n} S_d(T_n, \xi) = \frac{L_n}{M_n} \frac{T_n^2}{4\pi^2} S_a(T_n, \xi) \quad (17)$$

The maximum displacement and the equivalent lateral force of the j th storey will be

$$\begin{aligned} u_{n,\max}^j &= \frac{L_n}{M_n} S_d(T_n, \xi) \Phi_{nj} \\ &= \frac{L_n}{M_n} \frac{T_n^2}{4\pi^2} S_a(T_n, \xi) \Phi_{nj} \end{aligned} \quad (18)$$

$$s_{n,\max}^j = \frac{L_n}{M_n} m_j S_a(T_n, \xi) \Phi_{nj} \quad (19)$$

Alternatively, the maximum values of the member forces due to the n th mode can be obtained by static analysis by loading the structure with the maximum equivalent lateral forces of Eq. 19. The calculation would be

$$\mathbf{f}_n = \left(\frac{L_n}{M_n} \mathbf{m} \Phi_n \right) S_a(T_n, \xi) \quad (20)$$

and the modal displacements are obtained as $\mathbf{s}_{n,\max} = \mathbf{k}^{-1} \mathbf{f}_n$.

Modal Combination Rules

RSA provides only the maximum response parameter values of every mode. Once the maxima of every mode are known, we need to calculate the exact maximum value of a response quantity. This calculation is not straightforward. If the maximum value of every mode had occurred exactly at the same time instant, then combining Eqs. 3 and 17, we would get

$$\mathbf{u}_o = \sum_{n=1}^N \left| \frac{L_n}{M_n} \frac{T_n^2}{4\pi^2} \Phi_n S_a(T_n, \xi) \right| \geq \max(\mathbf{u}(t)) \quad (21)$$

The equation above provides a conservative estimation of $\mathbf{u}_{\max}$, since, as also shown in Fig. 2, the maxima of every mode do not occur concurrently. This upper bound is usually too conservative and rarely used for design. In practice, modal combination rules, as discussed in the next section, are preferred.

The Square Root of the Sum of Squares (SRSS) Rule

The most common rule for modal combination is the *Square Root of Sum of Squares* (SRSS) rule. According to this rule, the peak response of every mode is squared and then the squares are summed. The estimation of the maximum response quantity of interest is the square of the sum. If we denote r as an arbitrary response quantity (e.g., displacement, stress resultants) and r_n is its peak modal response, their SRSS combination is written as

$$r_o \approx \sqrt{r_1^2 + r_2^2 + \cdots + r_n^2} \quad (22)$$

In general, this combination rule gives good response estimates, especially for two-dimensional problems. The major limitation is that in order to produce satisfying estimates, the modes should be well separated, i.e., the eigenfrequencies should not have close values. If this condition is not met, the CQC method should be used instead. A criterion to determine if two modes are well separated is

$$\frac{1}{\beta_{nm}} \geq 1 + 0.1 \sqrt{\xi_n \xi_m} \quad (23)$$

where $\beta_{nm} = \omega_m/\omega_n = T_n/T_m$ and ξ_n, ξ_m is the damping ratio of modes n and m , respectively.

The Complete Quadratic Combination (CQC) Rule
The complete quadratic combination (CQC) rule overcomes the limitations of the SRSS rule and should be adopted if the condition of Eq. 23 is not satisfied. The rule is expressed as follows:

$$r_o \approx \sqrt{\sum_{n=1}^N \sum_{m=1}^N \epsilon_{nm} r_n r_m} \quad (24)$$

Response Spectrum Analysis of Structures Subjected to Seismic Actions, Fig. 7 (a) Displacement response spectrum, (b) acceleration response spectrum

where ϵ_{nm} is a correlation coefficient that takes values in the 0,1 range and is equal to 1 when

$n = m$. If β_{nm} is that of Eq. 23, the correlation term is calculated as

$$\epsilon_{nm} = \frac{8\sqrt{\xi_n \xi_m}(\xi_n + \beta_{nm}\xi_m)\beta_{nm}^{3/2}}{(1 - \beta_{nm}^2)^2 + 4\xi_n \xi_m \beta_{nm}(1 + \beta_{nm}^2) + 4(\xi_n^2 + \xi_m^2)\beta_{nm}^2} \quad (25)$$

If the same modal damping is used for modes n and m ($\xi_n = \xi_m = \xi$), the equation reduces to

$$\epsilon_{nm} = \frac{8\xi^2(1 + \beta_{nm})\beta_{nm}^{3/2}}{(1 - \beta_{nm}^2)^2 + 4\xi^2\beta_{nm}(1 + \beta_{nm}^2)} \quad (26)$$

Note that according to Eq. 26 when $\beta_{nm} = 1$, i.e., for two modes with equal frequencies, their correlation coefficient ϵ_{nm} is equal to 1. When the modes are well separated, the $n \neq m$ terms of ϵ_{nm} become very small and the CQC rule gives estimates very close to those of the SRSS rule. ϵ_{nm} can take both positive and negative values and the CQC estimate may be above or below that of SRSS. Further discussion on the CQC rule can be found in Der Kiureghian (1981) and Wilson et al. (1981).

Both the SRSS and the CQC method should be applied directly on the response quantity of

interest according to its modal value. Obtaining the value of a response quantity by combining the peak values of other quantities must be avoided as it may result to gross errors.

Example 2: Response Spectrum Modal Analysis of a Plane Frame For the building of Fig. 1a, estimate the storey displacements using response spectrum analysis. The structure is again subjected to the Imperial Valley ground motion record of Fig. 1b.

The spectral displacements and the spectral accelerations of the Imperial Valley (1979) ground motion record are shown in Fig. 7. We show both displacement and acceleration spectra for comparison (although the acceleration spectrum is always adopted in practice). The modal displacements $y_{n,\max}$ are calculated with either of the expressions of Eq. 17. Thus, for the first mode, we obtain:

$$\begin{aligned}
 y_{1,\max} &= \frac{L_n}{M_n} S_d(T_n, \xi) \\
 &= \frac{84.22}{72.62} \times 0.0486 = 0.056m, \text{ or} \\
 y_{1,\max} &= \frac{L_n}{M_n} \frac{T_n^2}{4\pi^2} S_a(T_n, \xi) \\
 &= \frac{84.22}{72.62} \frac{0.98^2}{4\pi^2} \times 0.203 \times 9.81 = 0.056m
 \end{aligned}$$

Similarly, we obtain $y_{2,\max} = 0.0018m$ and $y_{3,\max} = 0.0002m$ for the second and the third mode, respectively. Both methods yield practically the same value; the minor differences are due to round-off errors. These values should coincide with the maxima of Fig. 2. The differences observed are again due to round-off errors. Note that we have dropped the negative signs using the absolute values of all response quantities.

The modal displacements of the first mode are (Eq. 3)

$$\begin{aligned}
 \mathbf{u}_{1,\max} &= \Phi_1 y_{1,\max} = \begin{bmatrix} 0.69 \\ 0.92 \\ 1.0000 \end{bmatrix} \times 0.056 \\
 &= \begin{bmatrix} 0.0388 \\ 0.0519 \\ 0.0565 \end{bmatrix} m.
 \end{aligned}$$

The $\mathbf{u}_{n,\max}$ values are summarized in Table 2.

If the maxima of $\mathbf{u}_n(t)$ occurred at the same time instant, then we could apply Eq. 21 to get the maximum storey displacements. Although this is

not correct, it can be used to give a conservative upper bound. Therefore

$$\begin{aligned}
 \mathbf{u}_{\max} &< \left| \sum_{n=1}^N \Phi_n y_{n,\max} \right| \\
 &= |\Phi_1 y_{1,\max}| + |\Phi_2 y_{2,\max}| + |\Phi_3 y_{3,\max}| \\
 &= \begin{bmatrix} 0.69 \\ 0.92 \\ 1.0 \end{bmatrix} \times 0.0565 + \begin{bmatrix} 0.95 \\ 0.16 \\ 1.0 \end{bmatrix} \times 0.0018 \\
 &\quad + \begin{bmatrix} 0.38 \\ 0.83 \\ 1.0 \end{bmatrix} \times 0.0002 = \begin{bmatrix} 0.0403 \\ 0.0519 \\ 0.0580 \end{bmatrix} m.
 \end{aligned} \tag{27}$$

The above values clearly overestimate the actual values obtained with response history analysis which are shown in the last row of Table 2. For a more accurate and less conservative estimation of the maximum displacements, we use the SRSS or the CQC rule. A sample calculation of the top storey displacement using the SRSS rule will be

$$\mathbf{u}_{3,o} = \sqrt{0.0565^2 + 0.0018^2 + 0.0002^2} = 0.0565m.$$

For storeys 1 and 2, the maximum displacements are $\mathbf{u}_{1,o} = 0.0389m$ and $\mathbf{u}_{2,o} = 0.0519m$ (Table 2).

The CQC method requires first to calculate β_{nm} and ϵ_{nm} . The values of β_{nm} are shown in Table 3, and Table 4 shows ϵ_{nm} . A sample calculation of β_{12} would give $\beta_{12} = T_2/T_1 = 0.31/0.984 = 0.3123$. ϵ_{12} is obtained as

$$\epsilon_{12} = \frac{8 \times 0.05^2 \times (1 + 0.3123) \times 0.3123^{3/2}}{(1 - 0.3123^2)^2 + 4 \times 0.05^2 \times 0.3123 \times (1 + 0.3123)^2} = 0.005587 \tag{28}$$

Moreover, when $N = 3$, Eq. 24 becomes

$$\begin{aligned}
 r_o^2 &= r_1^2 + r_1^2 + r_2^2 + r_3^2 + (\epsilon_{12} + \epsilon_{21})r_1r_2 + \\
 &\quad + (\epsilon_{23} + \epsilon_{32})r_2r_3 + (\epsilon_{13} + \epsilon_{31})r_1r_3.
 \end{aligned}$$

With the aid of Table 4, the maximum displacement of the third storey becomes

$$\begin{aligned}
 u_{3,o}^2 &= 0.0565^2 + 0.0018^2 + 0.0002^2 \\
 &\quad + 2 \times 0.0056 \times 0.0565 \times 0.0018 \\
 &\quad + 2 \times 0.0592 \times 0.0018 \times 0.0002 \\
 &\quad + 2 \times 0.0026 \times 0.0565 \times 0.0002 \\
 &= 0.0032 + 1.4 \cdot 10^{-6} + 4.2 \cdot 10^{-8} + 5.9 \cdot 10^{-8} \\
 &= 0.0032 u_{3,o} = \sqrt{0.032} = 0.0565
 \end{aligned} \tag{29}$$

Response Spectrum Analysis of Structures Subjected to Seismic Actions, Table 2 Response spectrum modal displacements

	Storey 1	Storey 3	Storey 3
$u_{1,max}$	0.0388	0.0519	0.0565
$u_{2,max}$	0.0017	0.0003	0.0018
$u_{3,max}$	0.0001	0.0001	0.0002
Sum (Eq. 21)	0.0403	0.0519	0.0580
SRSS (Eq. 22)	0.0389	0.0519	0.0565
CQC (Eq. 24)	0.0389	0.0519	0.0565
RHA	0.0333	0.0468	0.0520

Response Spectrum Analysis of Structures Subjected to Seismic Actions, Table 3 β_{nm} values used for the CQC method

Mode	1	2	3
1	1.0000	0.3123	0.2110
2	3.2021	1.0000	0.6757
3	4.7396	1.4799	1.0000

Note that for the problem studied, the correlation terms are very small (less than 10^{-6}), and thus the final prediction is similar to that of the SRSS method. Also, cautiousness is required due to the fact that in the CQC calculation, the r terms maintain their sign (here, everything is positive). This means that the CQC estimates could be greater or smaller than that of SRSS.

Another approach to obtain the modal displacements is through applying the equivalent lateral forces of Eq. 20. For the first mode, the calculation will be

$$\begin{aligned} \mathbf{f}_1 &= \left(\frac{L_1}{M_1} \mathbf{m} \Phi_1 \right) S_a(T_1, \xi) \\ &= \frac{84.22}{72.62} \begin{bmatrix} 40 & 0 & 0 \\ 0 & 40 & 0 \\ 0 & 0 & 20 \end{bmatrix} \begin{bmatrix} 0.6870 \\ 0.9184 \\ 1.0000 \end{bmatrix} 0.202g \\ &= \begin{bmatrix} 63.3358 \\ 84.6704 \\ 46.0954 \end{bmatrix} \text{ kN.} \end{aligned}$$

The equivalent lateral forces are applied on the structure to the yield the modal displacements:

$$\mathbf{u}_1 = \mathbf{k}^{-1} \mathbf{f}_1 = \mathbf{k}^{-1} \begin{bmatrix} 63.3358 \\ 84.6704 \\ 46.0954 \end{bmatrix} = \begin{bmatrix} 0.0388 \\ 0.0519 \\ 0.0565 \end{bmatrix} m$$

Response Spectrum Analysis of Structures Subjected to Seismic Actions, Table 4 ϵ_{nm} values used for the CQC method

Mode	1	2	3
1	1.0000	0.0056	0.0026
2	0.0056	1.0000	0.0592
3	0.0056	1.0000	0.0592

The reader should appreciate that the base shear of the first mode, V_{s1} , is equal to the sum of the entries of $\mathbf{f}_1$, which yields $V_{s1} = 194.10 \text{ kN}$.

Multistorey Buildings with Arbitrary Plan Configuration

Response spectrum analysis has been so far discussed for plane frames. The extension to three-dimensional buildings, although straightforward, requires some further attention. When three-dimensional multistorey buildings are studied, we assume that each storey behaves as a rigid diaphragm with three inplane degrees of freedom, two translational, and one rotational. Therefore, the total number of degrees of freedom is $3N$, where N is the number of storeys. Moreover, the direction of seismic loading is arbitrary but can always be analyzed to two components parallel to the x and y axes and denoted $\ddot{u}_{g,x}$, $\ddot{u}_{g,y}$, respectively. The equation of motion (Eq. 1) is now written:

$$\tilde{\mathbf{m}} \begin{bmatrix} \ddot{\mathbf{u}}_x \\ \ddot{\mathbf{u}}_y \\ \ddot{\mathbf{u}}_\theta \end{bmatrix} + \tilde{\mathbf{c}} \begin{bmatrix} \dot{\mathbf{u}}_x \\ \dot{\mathbf{u}}_y \\ \dot{\mathbf{u}}_\theta \end{bmatrix} + \tilde{\mathbf{k}} \begin{bmatrix} \mathbf{u}_x \\ \mathbf{u}_y \\ \mathbf{u}_\theta \end{bmatrix} = -\tilde{\mathbf{m}} \begin{bmatrix} \ddot{u}_{g,x} \\ \ddot{u}_{g,y} \\ 0 \end{bmatrix} \quad (30)$$

where the mass matrix is

$$\tilde{\mathbf{m}} = \begin{bmatrix} \mathbf{m}_x & 0 & 0 \\ 0 & \mathbf{m}_y & 0 \\ 0 & 0 & \mathbf{I}_O \end{bmatrix} \quad (31)$$

and $\tilde{\mathbf{c}}$ and $\tilde{\mathbf{k}}$ are the corresponding damping and stiffness matrices, respectively. $\mathbf{I}_O$ is a diagonal matrix of order N whose entries are the moments of inertia of every storey about the vertical axis that passes through the center of mass. The modal

vector consists of three subvectors, $\Phi_n = \langle \phi_{xn} \phi_{yn} \phi_{\theta n} \rangle$, and the participation factor L_n^h/M_n is now calculated from the quantities:

$$\begin{aligned} L_{xn}^h &= \phi_{xn}^T \mathbf{m}, \text{ for } \ddot{u}_{gx} \\ L_{yn}^h &= \phi_{yn}^T \mathbf{m}, \text{ for } \ddot{u}_{gy} \end{aligned} \quad (32)$$

and

$$M_n = \Phi_n^T \tilde{\mathbf{m}} \Phi_n \quad (33)$$

K_n and C_n are defined as before using Eq. 4. Equation 32 depends on the component of ground motion considered ($\ddot{u}_{g,x}$ or $\ddot{u}_{g,y}$). For every mode, we solve again Eq. 7 to obtain the modal displacements y_n and the lateral displacements and the torsional rotation of the diaphragm:

$$\mathbf{u}_n = \langle \mathbf{u}_{xn} \mathbf{u}_{yn} \mathbf{u}_{\theta n} \rangle = \langle \phi_{xn} \phi_{yn} \phi_{\theta n} \rangle y_n(t) \quad (34)$$

The modal displacements can be obtained from the design response spectrum using Eq. 17 or performing static analysis of the building applying the equivalent static forces associated with the n^{th} mode peak response (Eq. 20). In this case, assuming $\ddot{u}_g = \ddot{u}_{gx}$, the lateral forces $\mathbf{f}_n$ will be

$$\mathbf{f}_n = \frac{L_{nx}}{M_n} \mathbf{m} \Phi_n S_a(T_n, \xi) \quad (35)$$

and

$$\mathbf{u}_n = \tilde{\mathbf{k}}^{-1} \mathbf{f}_n. \quad (36)$$

Response Spectrum Modal Analysis in Seismic Design Codes

Various design codes and guidelines, including European and US codes, suggest the use of both linear and nonlinear methods of analysis. Nonlinear methods are beyond the scope of this entry, while linear methods are based on response spectrum modal analysis and on a simplified method that considers only the first mode of response. According to the terminology of

Eurocode 8, linear elastic analysis can be performed either with (a) the “lateral force method of analysis” for buildings meeting specific conditions or (b) with the “modal response spectrum analysis,” applicable to all types of buildings and being the reference method for obtaining seismic response estimates.

According to the “lateral force method of analysis,” a lateral load pattern that follows the first mode is applied (e.g., Eq. 35). In Eurocode 8, the method is applicable only if the fundamental period of vibration is less than 2s or $4T_C$, where T_C is the corner period of the design spectrum. A second condition that also has to be satisfied is that the structure should meet the criteria for regularity in plan. Different criteria may be found in other codes. The “modal response spectrum analysis” is recommended for all other cases, with the only exception of buildings with seismic isolation provided by highly nonlinear devices. Practically every design code in the world uses these two methods for linear elastic analysis and recommends criteria to determine if their applicable.

Summary

Response spectrum modal analysis has been presented, discussing that it is a simplified version of modal analysis and appropriate for structural design. The method allows the use of smooth design spectra for the assessment and the design of structures. All concepts discussed are presented in a numerical example, while the adaptation of the method by modern design codes has been conceptually explained.

Introduction

Computational methods, such as the finite element method, are nowadays necessary for the analysis and design of large-scale engineering

systems. The considerable influence of inherent uncertainties on system behavior has also led the scientific community to recognize the importance of a stochastic approach to engineering problems. Engineering experience has shown that uncertainties are involved not only in the loading but also in the material and geometric properties of engineering systems. The rational treatment of these uncertainties cannot be addressed rigorously in the framework of the traditional deterministic approach. Stochastic methods do provide this possibility at the expense of increasing the complexity of the system model and, consequently, of the required computational effort for the solution of the problem. Therefore, the exploitation of the available computational resources and the development of enhanced solution algorithms are of paramount importance in the application of stochastic methods to real-world problems and to their further dissemination to the engineering community.

The problems of response variability and reliability of structures with stochastic properties under dynamic loading are currently the subject of extensive research in the fields of computational stochastic dynamics and earthquake engineering. Both problems deal with the computation of the statistical characteristics of the response (statistical moments, probability of failure), and their solution is time consuming, particularly in the case of large-scale realistic structures. An important practical application of structural response variability and reliability is the estimation of seismic fragility curves used to assess the vulnerability of structures due to earthquakes. Fragility curves provide the probability of exceeding a prescribed level of damage for a wide range of ground motion intensity, usually expressed in terms of peak ground or spectral accelerations.

The existing analytical methods for the evaluation of structural response variability and reliability can only be used in few special cases and are not applicable to realistic engineering problems. Therefore, this chapter will be focused on approximate methods and simulation. The first class of methods is mostly based on the

approximation of the underlying Fokker–Planck–Kolmogorov equation or of the limit state function, while the second comprises the direct Monte Carlo simulation and its variants. In sections “[Response Variability of Stochastic Systems](#)” and “[Reliability of Stochastic Systems](#),” distinction will be made between linear and nonlinear systems as the available techniques depend on structural characteristics. Nonlinear systems are significantly more involved, and their treatment requires the development of specialized approaches. A numerical example involving the computation of the response variability and reliability of a steel frame will be provided in the last section.

Response Variability of Stochastic Systems

Linear Systems

The case of stochastic linear systems will be examined first. The equation of motion of these systems in the time domain t is the following:

$$\mathbf{M}(\boldsymbol{\theta})\ddot{\mathbf{u}}(t, \boldsymbol{\theta}) + \mathbf{C}(\boldsymbol{\theta})\dot{\mathbf{u}}(t, \boldsymbol{\theta}) + \mathbf{K}(\boldsymbol{\theta})\mathbf{u}(t, \boldsymbol{\theta}) = \mathbf{F}(t, \boldsymbol{\theta}) \quad (1)$$

where $\mathbf{M}$, $\mathbf{C}$, $\mathbf{K}$ are the stochastic mass, damping, and stiffness matrices, respectively, and $\mathbf{u}$, $\dot{\mathbf{u}}$, $\ddot{\mathbf{u}}$ denote the stochastic displacement, velocity, and acceleration vectors of the structural system (parameter $\boldsymbol{\theta}$ denotes the randomness of a quantity).

Direct Monte Carlo simulation (MCS) is the simplest method for computing the dynamic response variability of stochastic structural systems. In this method, $NSIM$ samples of the stochastic system matrices are generated using a random number generator, and the equation of motion (Eq. 1) is solved $NSIM$ times, leading to a population (sample) of the response vector. Based on this population, the response variability of the system is calculated using simple relationships of statistics. For example, if u_i is the displacement at the i th d.o.f. of the discretized structure, then the unbiased estimates of the

mean value and variance of the corresponding sample are

$$E(u_i) = \frac{1}{NSIM} \sum_{j=1}^{NSIM} u_i(j) \quad (2)$$

$$\sigma^2(u_i) = \frac{1}{NSIM - 1} \left[\sum_{j=1}^{NSIM} u_i^2(j) - NSIM \cdot E^2(u_i) \right] \quad (3)$$

It is obvious that the accuracy of the estimation depends on the number of samples, and, in particular, the estimate of standard deviation σ is inversely proportional to $\sqrt{NSIM}$. A small number of samples, e.g., $NSIM \approx 50$, permits only a rough approximation of the mean value and variance of the response. With a larger sample size, e.g., $NSIM \approx 500$, it is possible to estimate the cumulative distribution function (CDF) of the response. A number of samples as large as 10^4 is usually needed in dynamical problems in order to compute the probabilistic characteristics of the response with sufficient accuracy. This leads to an excessive computational cost especially in the combined case of large-scale systems and of considerable stochastic dimension. However, the development of robust and efficient solution algorithms in conjunction with the increasing availability of powerful computers and the suitability of the method to parallel processing with ideal efficiency alleviates this limitation to a large extent (Johnson et al. 2003; Stefanou 2009).

The direct MCS described above is the basic version of the method and is often used in the literature as an exact (reference) approach for validating the results of other methods (Adhikari 2011). Several variants of this approach (e.g., importance sampling, subset simulation, line sampling) have been developed in the last twenty years especially for the efficient solution of reliability problems where the calculation of small failure probabilities requires a very large number of samples. These variants will be examined in section “[Reliability of Stochastic Systems](#).”

Recently, an exact nonstatistical method has been proposed for the dynamic analysis of finite

element (FE)-discretized uncertain linear structures in the frequency domain (Falsone and Ferro 2007). This procedure is based on the properties of the structural deformation modes and, in particular, on the number of principal deformation modes of the FE type used for the structural discretization. The method leads to an exact relationship between the response and the random variables representing the structural uncertainties and thus allows obtaining an optimum level of accuracy through a reduced computational effort.

An approximate method for the response variability calculation of dynamical systems with uncertain stiffness and damping ratio can be found in Papadimitriou et al. (1995). This approach is based on complex mode analysis where the variability of each mode is analyzed separately and can efficiently treat a variety of probability distributions assumed for the system parameters. A probability density evolution method (PDEM) has also been developed for the dynamic response analysis of linear stochastic structures (Li and Chen 2004). In this method, a probability density evolution equation (PDEE) is derived according to the principle of preservation of probability. With the state equation expression, the PDEE is further reduced to a one-dimensional partial differential equation from which the instantaneous probability density function (PDF) of the response and its evolution are obtained. Finally, variability response functions have been recently proposed as an alternative to direct MCS for the accurate and efficient computation of the dynamic response of linear structural systems with uncertain Young modulus (Papadopoulos and Kokkinos 2012).

Nonlinear Systems

The general form of the equation of motion for a multi-degree-of-freedom nonlinear system is the following:

$$\mathbf{M}(\boldsymbol{\theta})\ddot{\mathbf{u}}(t, \boldsymbol{\theta}) + \mathbf{f}_D(\mathbf{u}, \dot{\mathbf{u}}, t, \boldsymbol{\theta}) + \mathbf{f}_S(\mathbf{u}, \dot{\mathbf{u}}, t, \boldsymbol{\theta}) = \mathbf{F}(t, \boldsymbol{\theta}) \quad (4)$$

where $\mathbf{u}$, $\dot{\mathbf{u}}$, $\ddot{\mathbf{u}}$ denote the stochastic displacement, velocity, and acceleration vectors of the structural

system; $\mathbf{M}$ is the stochastic mass matrix; and $\mathbf{f}_D(\mathbf{u}, \dot{\mathbf{u}}, t, \boldsymbol{\theta})$, $\mathbf{f}_S(\mathbf{u}, \dot{\mathbf{u}}, t, \boldsymbol{\theta})$ are the damping and restoring force terms, which are usually nonlinear functions of the displacement and velocity of the system ($\boldsymbol{\theta}$ denotes the randomness of a quantity, as in Eq. 1).

In contrast to the linear case, the stochastic analysis of dynamic systems with nonlinear mechanisms involved either in the excitation process or in the mechanical properties poses a major challenge in the field of stochastic dynamics (Manolis and Koliopoulos 2001). This can be explained by the fact that most of the methods developed for the analysis of linear systems are inefficient or inappropriate for the nonlinear case. For example, the analysis of uncertain nonlinear systems is generally not feasible using frequency domain analysis techniques (Iwan and Huang 1996). Major research efforts in this area concentrate on the development of new and the adaption of existing methods to assess the stochastic response. In the past, analytical procedures dominated the developments in nonlinear stochastic dynamics, but in recent years, the emphasis has been placed on numerical methods, sometimes combined with analytical procedures. It is worth noting that the majority of earthquake engineering applications fall within this class of stochastic problems (Desceliers et al. 2004).

Most of the analytical solutions for nonlinear systems are based on the Fokker–Planck–Kolmogorov (FPK) diffusion equation:

$$\frac{\partial p}{\partial t} + \sum_{i=1}^N \frac{\partial}{\partial x_i} (a_i p) - \frac{1}{2!} \sum_{i=1}^N \sum_{j=1}^N \frac{\partial^2}{\partial x_i \partial x_j} (b_{ij} p) + \dots = 0 \quad (5)$$

where p represents the transition probability between states and a_i , b_{ij} represent the drift and diffusion terms depending in general on the state vector $\mathbf{x}$. These require an excitation process with broadband characteristics in order to be modeled by a white noise approximation, leading to Markovian properties. Exact solutions are available for a limited class of problems. Other solution methods, e.g., the FE method or the path integral

method, require extremely large computational efforts for systems of order higher than two. Alternative types of approximate methods, such as the stochastic averaging and statistical linearization techniques, are currently limited to systems with very few degrees of freedom (Schuëller 2006; Kougiumtzoglou and Spanos 2013).

The existing numerical methods for response statistics calculation are mostly based on simulation or on the perturbation approach (Schuëller and Pradlwarter 1999; Muscolino et al. 2003; Liu et al. 1986). Studies can also be found on the statistical equivalent linearization (EQL) method for the response variability and reliability estimation of discrete nonlinear systems (Schuëller and Pradlwarter 1999). It is well known that the main drawback of the perturbation approach is the significant loss of accuracy when the level of uncertainty of the system properties is high. On the other hand, the computational effort required by statistical approaches such as direct MCS for the analysis of large-scale structures is considerable thus making essential the use of efficient solution strategies and parallel processing. In addition, the validity of EQL is questionable in some cases, and the method may even produce misleading results (Bernard 1998). Alternatively, an extension of the PDEM has been developed for the dynamic response analysis of nonlinear stochastic structures (Li and Chen 2006).

Reliability of Stochastic Systems

The reliability analysis of structures under dynamic loading consists in the computation of the probability that a specific response quantity will not exceed a critical threshold at various time instants. The characteristics of the loading and material properties can be described in most cases with sufficient accuracy by utilizing the theory of stochastic processes and fields along with experimental data information for estimating the appropriate parameters. While for wind loading, and also in some cases for wave loading, linear structural models suffice, nonlinear models are definitely required for earthquake loading as explained in subsection “Nonlinear Systems.”

A recent comprehensive review on reliability assessment in structural dynamics can be found in Goller et al. (2013).

Linear Systems

The direct MCS examined in section “Response Variability of Stochastic Systems” becomes inefficient for the solution of reliability problems where a large number of low-probability realizations in the failure domain must be produced. In order to alleviate this problem without deteriorating the accuracy of the solution, numerous variants of this approach have been developed. An important class of improved MCS is variance reduction techniques where the generation of samples of the basic random variables is controlled in an efficient way.

The most prominent representative of this class of methods is importance sampling (IS), in which the generation of samples is controlled by a sampling distribution concentrated in the “important” (low-probability) region of the failure domain. The main challenge in the application of IS to physical problems is the determination of the sampling distribution, which depends on the specific system at hand and on the failure domain (Schuëller 2006). The optimal choice of the sampling distribution (for which the variance of the estimator of the probability of failure p_F vanishes) is practically infeasible since an a priori knowledge of p_F is required for this purpose. Thus, several techniques based on kernel density estimators or design points have been proposed in order to produce a sampling distribution characterized by a reduced variance of the estimator of p_F :

$$\hat{p}_F = \frac{1}{N} \sum_{i=1}^N \frac{1_F(\boldsymbol{\theta}^{(i)}) h(\boldsymbol{\theta}^{(i)})}{f(\boldsymbol{\theta}^{(i)})} \quad (6)$$

In this equation, N is the number of samples, 1_F denotes the indicator function of the failure domain, h is the joint probability distribution of the basic random variables, and the samples $\{\boldsymbol{\theta}^{(i)}\}_{i=1}^N$ are generated according to the sampling distribution f .

IS is efficient for the reliability assessment of static linear and nonlinear systems characterized by a small number of basic random variables. However, for the dynamic reliability analysis of large nonlinear systems in high stochastic dimensions, the computational effort needed to construct a suitable sampling distribution may exceed the effort required by the direct MCS (Schuëller 2006).

Apart from sampling-based algorithms, approximate methods have also been developed for the evaluation of the reliability of linear dynamical systems. Most of these methods are based on the solution of the FPK diffusion equation by means of the FE method or the path integral approach with the goal of determining the response PDF which is used for the estimation of the associated failure probability. Although these diffusion process-based methods provide accurate results, their application to large-scale structural systems is limited. Therefore, some recent research efforts focus on the enhancement of the PDEM (see section “Response Variability of Stochastic Systems”) for large-scale structural reliability estimation. The first-order reliability method (FORM) is also frequently applied in the field of dynamics. The basic idea of this approach is the approximation of the limit state function by a hyperplane through the so-called design point, i.e., the point on the limit state function with the minimum distance to the origin. However, due to the underlying assumption of a single failure region with a linear performance function, the accuracy of FORM in the reliability assessment of dynamical systems is often not satisfactory (Goller et al. 2013). Finally, an efficient IS technique is combined in Jensen and Valdebenito (2007) with approximate representations of performance functions for the reliability analysis of linear dynamical systems.

Nonlinear Systems

The reliability analysis of nonlinear systems is defined similarly to the linear case as the computation of first excursion probabilities over specified thresholds. While in linear problems these thresholds are specified in terms of

displacements, the reliability thresholds of nonlinear responses might be more appropriately specified in terms of damage caused by excessive strains. Since most types of materials are characterized by a nonlinear stress–strain relationship and deteriorating strength, nonlinear analysis is the correct choice to assess the structural reliability under severe loading conditions, such as earthquakes.

Direct MCS is the most general method for the reliability analysis of nonlinear systems, where the accuracy and efficiency are independent from the number of random quantities and the structural model type, and depends only on the number of generated samples (see section “Response Variability of Stochastic Systems”). However, a very large number of samples is required for the accurate computation of small failure probabilities (in the range of $10^{-7} < p_F < 10^{-4}$) thus making direct MCS inefficient in practice. In order to overcome the inefficiency of direct MCS in calculating small failure probabilities, a novel approach called subset simulation (SS) has been proposed by Au and Beck (2001). SS is a powerful tool, simple to implement, and capable of solving a broad range of reliability problems, e.g., Au and Beck (2003). The basic idea of SS is to express the failure probability p_F as a product of larger conditional probabilities by introducing a decreasing sequence of intermediate failure events (subsets): $\{F_i\}_{i=1}^m$ such that $F_m = F$ and $F_1 \supset F_2 \dots \supset F_m = F$:

$$p_F = P(F_m) = P(F_1) \prod_{i=1}^{m-1} P(F_{i+1}/F_i) \quad (7)$$

With a proper choice of the intermediate events, the conditional failure probabilities can be made sufficiently large. Therefore, the original problem of computing a small failure probability is reduced to calculating a sequence of larger conditional probabilities, which can be efficiently estimated by means of direct MCS with a small number of samples.

Another recently developed technique which permits the efficient treatment of high-dimensional reliability problems is line sampling (LS) (Koutsourelakis et al. 2004). This technique

Response Variability and Reliability of Structures,

Fig. 1 A three-story steel frame (With kind permission from Springer Science + Business Media: (Stefanou and Fragiadakis 2011), © Springer Science + Business Media B.V. 2011)

takes advantage of an implicitly available performance function (data points on the limit state surface) obtained directly from FE analyses. As already mentioned in the case of IS, the optimal choice of the sampling distribution is practically infeasible. However, something quite close to optimal sampling can be achieved by using LS and computing an important direction α which points toward the failure domain nearest to the origin. Neither the vector α is required to point exactly to the design point, nor are any assumptions made with respect to the shape of the limit state surface. In contrast to IS, where an inappropriate choice of the sampling distribution leads to worse estimates compared to direct MCS, LS performs at least as well as direct MCS even in the worst possible case where the direction α is selected orthogonal to the optimal direction (Koutsourelakis et al. 2004). In comparison to IS, LS requires far less performance evaluations (FE analyses) to obtain a similar accuracy. The advantages of LS become more pronounced in high stochastic dimensions as it is shown in Schuëller et al. (2004) where a comparison between different approaches for reliability estimation is presented.

The PDEM can also be efficiently applied to compute the probability density of the response of dynamically excited nonlinear structures (Li et al. 2012). It is finally worth noting that the theory of non-Gaussian translation processes has been applied directly to the reliability analysis of dynamic systems under limited information. This method delivers accurate results for the case of linear and nonlinear dynamic systems

assuming stationary output but can be easily extended to a special class of nonstationary, non-ergodic output (Field and Grigoriu 2009).

A Numerical Example

In this section, the response variability and reliability of a three-story steel moment-resisting frame shown in Fig. 1 are computed using direct MCS (Stefanou and Fragiadakis 2011). The frame has been designed for a Los Angeles site, following the 1997 NEHRP (National Earthquake Hazard Reduction Program) provisions in the framework of the SAC/FEMA program (SAC 2000). The dynamic response of the building is dominated by the fundamental mode which has a period value equal to $T_1 = 1.02$ s when the mean value of the modulus of elasticity is used. Response history analyses are performed using a force-based, beam-column fiber element implemented on a general purpose FE program (Taylor 2000). Geometric nonlinearities are not considered in the analysis. Rayleigh damping is used to obtain a damping ratio of 2 % for the first and the fourth mode. The material law is considered to be bilinear with pure kinematic hardening (with unloading and reloading branches parallel to the elastic stiffness). The applied gravity loading is 32.22 kN/m for the first two stories and 28.76 kN/m for the top story. These values are also used to obtain the nodal masses resulting to a lumped mass matrix.

Three sets of five strong ground motion records are used as input to the nonlinear dynamic procedure (Table 1). The three sets correspond to

three levels of increasing hazard: low, medium, and high. The chosen records differ in terms of amplitude, frequency content, duration, etc., and therefore, this variability is expected to be transferred to the statistics of the analysis, producing significant record-to-record variability. The 15 natural records are used as input to the analysis in order to compute the mean response quantities, the dispersion, and the reliability of the frame for the three intensity levels.

The spatial variability in Young modulus and yield stress of the frame is described by two uncorrelated 1D homogeneous non-Gaussian translation stochastic fields with zero mean and coefficient of variation (COV) equal to 0.10. A slightly skewed shifted lognormal distribution defined in the range $[-1, +\infty]$ is assumed for the two stochastic fields. E and σ_y are simultaneously varying in all the cases examined. The spectral density function of the underlying Gaussian field is given by

$$S_{gg}(\kappa) = \frac{\sigma_g^2 b}{2\sqrt{\pi}} \exp\left(-\frac{b^2 \kappa^2}{4}\right) \quad (8)$$

where σ_g denotes the standard deviation of the stochastic field and b is a parameter that

influences the shape of the spectrum and is proportional to the correlation length of the stochastic field.

The representative response quantity whose statistics are monitored is the maximum interstory drift $\theta_{\max}$. This parameter is a well-known engineering demand parameter that captures the seismic demand and its distributions along the height of the structure. The response statistics are calculated using 1000 Monte Carlo simulations. This number of simulations represents sufficiently well the prescribed first two moments of the response, while as shown in Fig. 2, statistical convergence is practically achieved after 400 simulations. The same trend was observed for all ground motions considered. The sensitivity of $\theta_{\max}$ with respect to the scale of correlation of the stochastic fields, quantified with the aid of the correlation length parameter b , is examined for the ground motions of the three sets. For this purpose, several sets of sample functions of E and σ_y are generated, each for a different value of parameter b . Six representative values of b varying from weak to strong correlation are considered ($b = 0.2, 1.0, 2.0, 10, 20$ and 100).

Response Variability and Reliability of Structures,

Fig. 2 Statistical convergence of mean and COV of maximum interstory drift $\theta_{\max}$ – lognormal distribution of E , σ_y with COV = 0.1 (With kind permission from Springer Science + Business Media: (Stefanou and Fragiadakis 2011), © Springer Science + Business Media B.V. 2011)

Based on Fig. 3, an important observation can be made regarding the variability of $\theta_{\max}$. In contrast to the static case where the displacement variability shows always the same trend, starting from small values for small correlation lengths corresponding to white noise stochastic fields up to large values for large correlation lengths, the COV of $\theta_{\max}$ varies significantly not only with the correlation length b but also in different ways among the records of the same intensity level (Fig. 3b). In some cases, the effect of b becomes negligible, and then the record-to-record variability is predominant (e.g., records 1/1, 5/1, and 3/3). In addition, a large magnification of uncertainty is observed in some cases, which is more pronounced for records 1/1, 4/1, 4/2, and 5/2, where the response COV tends to values that are 1.4–1.8 times greater than the corresponding input COV ($=0.1$). In contrast, the mean value of drift, although presenting an important record-to-record variability, is practically not affected by the correlation length parameter b (see Fig. 3a).

The skewness of $\theta_{\max}$ has been also calculated and is depicted in Fig. 4 where a significant influence of the correlation length parameter b and an important record-to-record variability can be observed. The values of skewness obtained in

each record and seismic intensity are substantially different from the skewness of the lognormal distribution describing the material properties (which is equal to 0.30) thus underlying the strong nonlinearity of the problem that causes a significant change in the statistical moments (and distribution) of the response.

The reliability of the frame can finally be calculated. Fig. 5 shows the CDF of $\theta_{\max}$ of record 4/2 for two different values of $b = 1, 100$. If the reliability of the frame is defined as the maximum interstory drift not exceeding a threshold, e.g., 6.5×10^{-3} , the reliability can be obtained from Fig. 5 for both cases of b as 0.915 and 0.555, respectively. It is worth noting that the reliability is substantially smaller in the second case. Fig. 6 shows the PDF of $\theta_{\max}$ of record 4/2 for the same two values of b . Simultaneously shown are the normal and lognormal distributions with a mean and standard deviation identical to those of the computed PDF and the extreme value distribution with the same mean as that of the computed PDF. It can be observed that these widely adopted probability distributions are quite different from the real PDF of the response, which clearly has a bimodal form especially in the case of small correlation length.

Summary

The problems of response variability and reliability of structures with stochastic properties under dynamic loading are currently the subject of extensive research in the fields of computational stochastic dynamics and earthquake engineering. Both problems deal with the computation of the statistical characteristics of the response and have important practical applications, such as the estimation of seismic fragility curves which are used to assess the vulnerability of structures due to earthquakes. As the existing analytical methods for the evaluation of structural response variability and reliability can only be used in few special cases, this chapter is mainly focused on approximate methods and simulation. A numerical example involving a steel frame is also provided to illustrate the presented theoretical concepts.

Artificial accelerograms; Earthquake modelling; Gaussian process; Nonstationary earthquakes; Simulation; Stochastic; Spectrum compatible

Introduction

Several problems of engineering interest require the use of ground motion time histories to analyze and design relevant structures. Recorded and artificial time histories can be both used for this purpose. The use of recorded time histories presents certainly some benefits but they might provide misleading information if used without appropriate consideration. As also it is rarely possible to collect a sufficient number of records in a given location, the use of artificial time histories presents a valuable strategy for the seismic

analysis and design of structures. The use of artificial earthquakes is allowed by international seismic codes (see e.g., Eurocode 8 2010). On the other hand, seismic codes do not provide the method to follow in order to generate artificial accelerograms, but provide only general conditions to be fulfilled in the professional practice. Specifically, seismic codes allow practitioners to employ artificial accelerograms in the seismic assessment and design of structures if the mean response spectrum calculated from each individual artificial time history matches the target response spectrum within a prefixed tolerance over a fixed range of frequencies. The conditions imposed by the seismic codes lead clearly to an inverse problem whose solution is not single. Various approaches can be used to address this problem, and in the last four decades, a plethora of methods has been proposed. Ground motion arising from seismic waves is a phenomenon that generally cannot be described in a deterministic fashion, being in its own nature randomly variable in space and time. The seismic waves resulting from the occurrence of an earthquake are affected by several factors (i.e., source patterns, path, site effects, etc.), as a consequence only a probabilistic approach provides a rigorous representation of the resulting action. The definition of which hypothesis and methods address more realistically the description of the ground motion phenomenon is still an open discussion in the scientific community.

Due to the random nature of the seismic action, the ground motion acceleration $\ddot{u}_g(t)$ recorded at a given location can be seen as a sample of a zero-mean stochastic process. In this regard a number of stochastic models have been proposed in literature and mainly categorized as Gaussian or non-Gaussian models (see Shinozuka and Deodatis 1988). Due to their relative simplicity, the Gaussian models are the most used. It is well known that a zero-mean Gaussian stochastic process is fully defined by the knowledge of the correlation function $R(t_1, t_2)$ or by the generally known power-spectral density function (PSD) $S(\omega, t)$. The latter is commonly preferred due to its physical interpretation related to the energy of the earthquake process

that is highly relevant for design applications. Moreover the one-sided (called also unilateral) power-spectral density function $G(\omega, t)$ is extensively used in literature, and according to the theory of the evolutionary spectra (Priestley 1981), it can be written as follows:

$$\begin{aligned} G(\omega, t) &= 0 & \omega < 0, \\ G(\omega, t) &= 2S(\omega, t) = |a(\omega, t)|^2 G(\omega) & \omega \geq 0; \end{aligned} \quad (1)$$

where $a(\omega, t)$ is the frequency dependent modulating function while $G(\omega)$ is the one-sided power-spectral density function of the stationary counterpart of $\ddot{u}_g(t)$. The processes defined by the evolutionary power-spectral density (EPSD) function in Eq. 1 enable to feature the ground motion acceleration by retaining both amplitude and frequency variation with time, generally these processes are known as fully nonstationary (or non-separable). In the case in which only the amplitude of the process varies with respect to time (i.e., $a(\omega, t) = a(t)$), the process is generally known as quasi-stationary (or separable or also uniformly modulated). Accordingly, Eq. 1 for quasi-stationary processes modifies as follows:

$$\begin{aligned} G(\omega, t) &= 0, & \omega < 0; \\ G(\omega, t) &= 2S(\omega, t) = |a(t)|^2 G(\omega), & \omega \geq 0. \end{aligned} \quad (2)$$

It is observed that the adoption of the time-amplitude nonstationarity through the modulating functions implies an empirically based decision-making process. Several authors proposed modulating functions generally calibrated on different arrays of accelerograms. Among the proposed modulating functions, probably the most diffused are that one proposed by Shinozuka and Sato (1967):

$$a(t) = \delta[\exp(-\beta_1 t) - \exp(-\beta_2 t)]; \beta_1, \beta_2 > 0, \beta_1 < \beta_2 \quad (3)$$

with

$$\delta = \beta_1/(\beta_2 - \beta_1) \exp[\beta_2/(\beta_2 - \beta_1) \ln(\beta_2/\beta_1)] \quad (4)$$

and the following one proposed by Iwan and Hou (1989):

$$a(t) = \delta t^m \exp(-\beta_3 t); \quad m, \beta_3 > 0 \quad (5)$$

$\delta = (\beta_3/m)^m \exp(m)$ that extended the analytical formula proposed by Hsu and Bernard (1978) defined for $m = 1$. Furthermore Jennings et al. (1969) proposed a piecewise modulating function given by the following formula:

$$a(t) = \begin{cases} \left(\frac{t}{t_1}\right)^2 & t < t_1 \\ 1 & t_1 \leq t \leq t_2 \\ \exp[-\beta_4(t - t_2)] & t > t_2 \end{cases} \quad (6)$$

extensively used in the generation of artificial earthquakes because it possesses a stationary time window of duration $T_s = t_2 - t_1$.

Finally, in the particular case in which the modulating function presented in Eq. 2 figures as $a(t) = 1$, the process is called stationary. Note that in this case the power-spectral density function depends only on the circular frequency and not on the time.

Once the power-spectral density function $G(\omega, t)$ is defined, the r th sample of ground acceleration process can be generated via the superposition of N harmonics as follows (e.g., Shinozuka and Deodatis 1988):

$$\ddot{u}_g^{(r)}(t) = \sum_{i=1}^N \sqrt{2G(i\Delta\omega, t)\Delta\omega} \cos(i\Delta\omega t + \varphi_i^{(r)}) \quad (7)$$

where $\Delta\omega$ is the size interval of the discretized frequency domain, $G(i\Delta\omega, t)$ is the power-spectral density function, and $\varphi_i^{(r)}$ are independent random phases uniformly distributed over the interval $[0, 2\pi)$.

The mean of the simulated response spectra obtained from the artificial accelerograms generated by Eq. 7 has to be compared to the response spectra defined by the seismic codes. If the recommended criteria are satisfied, the time histories can be used for design purposes (i.e., these are spectrum compatible).

Clearly, the proper definition of the power-spectral density function is the crucial step to address the stochastic modeling of the seismic action. In the context of defining spectrum-compatible ground motion processes, the issue consists in determining which is the inverse relationship between the power-spectral density function and the target response spectrum. It has to be emphasized that the evaluation of the response-spectrum-compatible power-spectral density function possesses the twofold aspects: (i) allowing the generation of artificial accelerograms through Eq. 7 and (ii) allowing the direct stochastic analysis.

The following sections are devoted to the review of the most relevant models of ground motion acceleration processes aimed to satisfy the code requirements. Namely, the stationary, quasi-stationary, and fully nonstationary as well as spatially variable stochastic spectrum-compatible ground motion will be discussed.

Stationary/Quasi-stationary Models

The most dated models of ground motion process rely on the simplistic hypothesis that only the energy of the ground motion varies with respect to time. According to this hypothesis the quasi-stationary models can reliably represent the ground motion process. Due to the separable feature of the power-spectral density function, the study of the quasi-stationary processes is generally addressed modeling independently the stationary counterpart from the modulating function (see e.g., Eq. 2). This approach is clearly approximated, but it has been shown of being able to provide accurate results. In this framework several procedures have been proposed in literature in order to determine spectrum-compatible power-spectral density functions. Herein the models proposed by Vanmarcke and Gasparini (1977), Kaul (1978), Sundararajan (1980), Pfaffinger (1983), Preumont (1980); Der Kiureghian and Neuenhofer (1992), Park (1995), and Cacciola et al. (2004) are addressed. The list is not fully comprehensive and the readers can refer to the review papers from Ahmadi (1979) and Cacciola (2011) for further references.

Problem Position

In order to address the problem of simulating artificial accelerograms compatible to a given response spectrum, firstly it is necessary to determine the generally known response-spectrum-compatible power-spectral density function. Under the hypothesis of zero-mean Gaussian stationary ground motion process, Vanmarcke and Gasparini (1977) pointed out the fundamental relationship between the target response spectrum and the power-spectral density function of the ground motion through the generally known “first passage problem,” that is,

$$RSA(\omega_0, \zeta_0) = \omega_0^2 \eta_U(T_s; p) \sigma_U \quad (8)$$

where $RSA(\omega_0, \zeta_0)$ is the pseudo-acceleration response spectrum for a given damping ratio ζ_0 and natural circular frequency ω_0 , η_U is the dimensionless peak factor, T_s is the time observing window, p is the not-exceeding probability, and σ_U is the standard deviation of the displacement response, which corresponds to the square root of the zero-order stationary spectral moment $\lambda_{0,U}$. The latter is in turn a function of the power-spectral density function of the ground motion through the following general formula:

$$\lambda_{i,U}(t) = \int_0^\infty \omega^i |H(\omega)|^2 G(\omega) d\omega \quad i = 0, 1, 2 \quad (9)$$

where $|H(\omega)|^2 = \left((\omega_0^2 - \omega^2)^2 + 4\zeta_0^2 \omega_0^2 \omega^2 \right)^{-1}$ is the energy transfer function of the single degree of freedom system of natural frequency ω_0 and damping ratio ζ_0 and $G(\omega)$ is the stationary response-spectrum-compatible power-spectral density function to be determined.

In the last four decades, Eq. 8 has been used by several authors to define the spectrum-compatible power-spectral density function. The methods proposed in literature mainly differentiate one from another for the hypothesis adopted to define the peak factor and for the approximations involved in the evaluation of the response spectral moments.

State of the Art for the Available Solutions

The authors who firstly introduced the implicit relationship for the evaluation of the response-spectrum-compatible power-spectral density function were Vanmarcke and Gasparini (1977); the formula proposed is nowadays still used by researchers and practitioners. To reach this objective Vanmarcke and Gasparini (1977) proposed an approximate expression of the standard deviation of the response displacement:

$$\sigma_U \simeq \frac{1}{\omega_0^2} \left\{ \left[G(\omega_0) \omega_0 \left(\frac{\pi}{4\zeta_0} - 1 \right) \right] + \int_0^{\omega_0} G(\omega) d\omega \right\}^{1/2} \quad (10)$$

Equation 10 is determined under the hypothesis of small damping ratio ζ_0 and approximating the energy transfer function with its value $|H(0)|^2 = 1/\omega_0^4$ in the range of frequencies between 0 and ω_0 . Furthermore they adopted the peak factor expression provided under the hypothesis of independent outcrossing of given barriers (see, e.g., Vanmarcke 1976), through its upper bound value (relatively to damping higher than 10 %), that is,

$$\eta_{U, \text{upp}} = \sqrt{2 \ln \left(\frac{2N_U}{-\ln p} \right)} \quad (11)$$

and for a lower bound valid for undamped systems

$$\eta_{U, \text{low}} = 1 + 0.25 \ln \left(\frac{N_U}{-\ln p} \right) \quad (12)$$

In Eqs. 11 and 12, p is the value of the exceeding probability chosen equal to 0.5 determining the median value of the peak factor; it is noted that the assumption of $p = 0.5$ introduces a further approximation that the median coincides with the mean value. N_U is the number of outcrossings of the given barrier over the fixed time window T_s assumed equal to the strong motion phase of the ground motion process, given by

$$N_U = v_U T_s \quad (13)$$

where v_U is the mean outcrossing rate of the zero level, that is,

$$v_U = \frac{1}{2\pi} \sqrt{\frac{\lambda_{2,U}}{\lambda_{0,U}}} \quad (14)$$

in which $\lambda_{0,U}$ and $\lambda_{2,U}$ are, respectively, the zeroth and the second-order spectral moments of the response process as defined in Eq. 9. Furthermore, the dependence of the peak factor from the power-spectral density function of the response is overcome by approximating the response spectral moments with their solution for the white noise input leading to the formula

$$N_U \simeq \frac{\omega_0}{2\pi} T_s \quad (15)$$

Finally the stationary spectrum-compatible unilateral power-spectral density function can be expressed by using Eqs. 8, 10, and 11 as follows:

$$G(\omega_0) = \frac{1}{\omega_0 \left(\frac{\pi}{4\zeta_s} - 1 \right)} \left[\frac{RSA^2(\omega_0, \zeta_0)}{\eta_U^2} - \int_0^{\omega_0} G(\omega) d\omega \right] \quad (16)$$

in which also the damping ratio ζ_0 has been substituted with the fictitious damping ζ_s to take into account of the transient part of the response process

$$\zeta_s = (1 - e^{2\zeta_0 \omega_0 t})^{-1} \zeta_0 \quad (17)$$

which tends to the natural damping of the oscillator once the steady-state response has developed.

Furthermore, the two authors developed the computer software SIMQKE (Gasparini and Vanmarcke 1976) providing a practical tool to simulate time histories from a spectrum-compatible power-spectral density function which is implemented as

$$G(\omega_i) = \frac{4\zeta_s}{\omega_i \pi} \left(\frac{RSA^2(\omega_i, \zeta_0)}{\eta_U^2} - \Delta\omega \sum_{k=1}^{i-1} G(\omega_k) \right) \quad (18)$$

in which a more accurate expression of the peak factor is adopted under the hypothesis of barrier outcrossings in clumps, that is,

$$\eta_U(\omega_0, \zeta_0) = \sqrt{2 \ln \left\{ \frac{\omega_0 T_s}{\pi(-\ln p)} \left[1 - \exp \left[-\delta_U \sqrt{\pi \ln \left(\frac{\omega_0 T_s}{\pi(-\ln p)} \right)} \right] \right] \right\}} \quad (19)$$

where δ_U is the spread factor measuring the narrowness of the power-spectral density function of the response process defined in the range between 0 and 1 and approximated by the following expression for white noise input process:

$$\delta_U = \sqrt{1 - \frac{\lambda_{1,U}^2}{\lambda_{0,U} \lambda_{2,U}}} \simeq \sqrt{\frac{4\zeta_0}{\pi}} \quad (20)$$

After selecting a time-modulating function, the software employs the proposed power-spectral density function for simulating synthetic accelerograms via superposition of random harmonic functions through Eq. 7.

Another contribution has been provided by Kaul (1978); in order to provide a simplified expression of the power-spectral density function compatible with a given response spectrum, the author adopted the peak factor in Eq. 11 in conjunction with the hypothesis that the response spectral moments are determined under the hypothesis of white noise input process. Therefore, N_U is determined according to Eq. 15 and the zero-order response spectral moments is given as follows:

$$\lambda_{0,U} \simeq \frac{\pi}{4\zeta_0 \omega_0^3} G(\omega_0) \quad (21)$$

After some simple algebra the following stationary power-spectral density function is determined:

$$G(\omega_0) = \frac{4\zeta_e}{\pi \omega_0} \frac{RSA^2(\omega_0, \zeta_0)}{\eta_U^2} \quad (22)$$

where the damping of the oscillator has been adjusted as suggested by Rosenblueth and Elorduy (1969) as follows:

$$\zeta_e = \zeta_0 + \frac{2}{\omega_0 t_f} \quad (23)$$

in which t_f is the time duration of the stochastic process. As Kaul assumed the process as stationary t_f is coincident with T_s .

Equation 23 has been used by Der Kiureghian and Neuenhofer (1992) in order to investigate a response spectrum methodology for multi-support seismic excitation, in which a constant value of the peak factor was adopted. Currently their stationary power-spectral density function formula is adopted in Eurocode 8 part 2 (2010), recommended for the seismic analysis of bridges, that is,

$$G(\omega_0) = 2\omega_0^2 \left(\frac{2\zeta_0 \omega_0}{\pi} + \frac{4}{\pi T_s} \right) \left[\frac{RSD^2(\omega_0, \zeta_0)}{2.5^2} \right] \quad \omega \geq 0 \quad (24)$$

where $RSD(\omega_0, \zeta_0) = RSA(\omega_0, \zeta_0)/\omega_0^2$ is the displacement response spectrum.

Sundararajan (1980) introduced an iterative method for defining the spectrum-compatible power-spectral density function, differently from the direct approaches followed by Vanmarcke and Gasparini (1977), Kaul (1978), and Der Kiureghian and Neuenhofer (1992). The iterative procedure established by Sundararajan (1980) starts from a trial solution of the first passage problem given in Eq. 8 and variance of the response process given by Eq. 21:

$$G(\omega_0) = \frac{4\zeta_0 \omega_0}{\pi} \frac{RSV^2(\omega_0, \zeta_0)}{\eta_U^2} \quad (25)$$

where $RSV(\omega_0, \zeta_0) = RSA(\omega_0, \zeta_0)/\omega_0$ is the velocity response spectrum and the peak factor is assumed independent of the input according to the hypothesis of small damping. Both Davenport (1964) and Amin and Gungor (1971) formulae

have been considered suitable to this purpose. However, in the numerical analysis conducted by the authors, a constant value $\eta_U = 3$ has been selected.

After determining the first trial solution of the power-spectral density function approximate as piecewise of linear functions, the author expressed the variance of the displacement response accordingly as

$$\sigma_U = \sum_{k=0}^N \int_{\omega_k}^{\omega_{k+1}} \frac{G(\omega)}{(\omega_0^2 - \omega^2)^2 + 4\zeta_0^2 \omega_0^2 \omega^2} d\omega \quad k = 1, \dots, N \quad (26)$$

in which the integrals have been determined in closed form, that is,

$$\int_{\omega_k}^{\omega_{k+1}} \frac{G(\omega)}{(\omega_0^2 - \omega^2)^2 + 4\zeta_0^2 \omega_0^2 \omega^2} d\omega = \frac{G_k}{(\omega_{k+1} - \omega_k)} [\omega_{k+1} J(\omega_k, \omega_{k+1}) - K(\omega_k, \omega_{k+1})] + \frac{G_k}{(\omega_{k+1} - \omega_k)} [\omega_k J(\omega_k, \omega_{k+1}) - K(\omega_k, \omega_{k+1})] \quad (27)$$

where $J(\omega_k, \omega_{k+1})$ and $K(\omega_k, \omega_{k+1})$ are the solutions of the integrals given by the following equations

$$J(\omega_k, \omega_{k+1}) = \int_{\omega_k}^{\omega_{k+1}} \frac{1}{(\omega_0^2 - \omega^2)^2 + 4\zeta_0^2 \omega_0^2 \omega^2} d\omega \quad (28)$$

$$K(\omega_k, \omega_{k+1}) = \int_{\omega_k}^{\omega_{k+1}} \frac{\omega_0}{(\omega_0^2 - \omega^2)^2 + 4\zeta_0^2 \omega_0^2 \omega^2} d\omega \quad (29)$$

and determined analytically. The iterative procedure proceeds by comparison of the target response spectrum and the approximate response spectrum evaluated through the semi-analytical expression of the variance of the response displacement. The values G_k are then updated scaling their values by the ratio of the square of the target response spectrum and the approximate response spectrum.

In the same year Preumont (1980) coupled direct and iterative solutions in order to solve the inverse problem of spectrum-compatible ground motion processes obtained from given response spectra; following the approach used

by Kaul and Sundararajan, the suggested solution is given as

$$G(\omega_0) = \frac{4\zeta_e}{\pi\omega_0} \frac{RSA^2(\omega_0, \zeta_0)}{\eta_U^2} \quad (30)$$

in which the semiempirical peak factor given in Eqs. 19 and 20 but considering the adjusted spread factor $\delta_U^{1,2}$ (Vanmarke 1972) is employed. The fictitious damping ζ_e given by Eq. 17 is also used.

The approximate solution given in Eq. 30 provides accurate results for low and intermediate frequencies. Therefore the author considered the solution proposed by Vanmarcke and Gasparini (1977) given by Eq. 10 with the adjusted spread factor as further improvement of Eq. 19. As the peak factor evaluation depends on the whole power-spectral density function, which is intrinsically related to the spectral characteristics of the unknown response process (see Eqs. 9, 13, 14, and 20), the author developed an algorithm which enables to update the spectral characteristics of the response process every frequency step of definition of the frequency domain. The iterative scheme mainly differs from the procedure proposed by Sundararajan (1980) as not only the zeroth-order spectral moment is updated at each step but also the peak factor. To this aim the

first- and second-order spectral moments are also updated in the iterative scheme, using a stepwise representation of the power-spectral density function as

$$G(\omega_k) = \frac{1}{2} [G(\omega_k) + G(\omega_{k+1})] \quad k = 1, \dots, N \quad (31)$$

The spectral moments of the response are analytically determined according to the following formula

$$\lambda_{i,U} = \sum_{k=1}^N \int_{\omega_k}^{\omega_{k+1}} \frac{\omega^i G(\omega)}{(\omega_0^2 - \omega^2)^2 + 4\zeta_0^2 \omega_0^2 \omega^2} d\omega \quad k = 1, \dots, N \quad (32)$$

and approximating the first term for $i = 0, 1, 2$, as

$$\lambda_{0,U} = \int_{\omega_k}^{\omega_{k+1}} |H(\omega)|^2 G(\omega) d\omega \simeq \frac{\pi G(\omega_0)}{4\zeta_0 \omega_0^3} \varphi(\omega_k, \omega_{k+1}, \omega_0, \zeta_0) \quad (33)$$

$$\lambda_{1,U} = \int_{\omega_k}^{\omega_{k+1}} |H(\omega)|^2 G(\omega) d\omega \simeq \frac{\pi G(\omega_0)}{4\zeta_0 \omega_0^2 \sqrt{1 - \zeta_0}} \theta(\omega_k, \omega_{k+1}, \omega_0, \zeta_0) \quad (34)$$

$$\lambda_{2,U} = \int_{\omega_k}^{\omega_{k+1}} |H(\omega)|^2 G(\omega) d\omega \simeq \frac{\pi G(\omega_0)}{4\zeta_0 \omega_0} \psi(\omega_k, \omega_{k+1}, \omega_0, \zeta_0) \quad (35)$$

where $\varphi(\omega_k, \omega_{k+1}, \omega_0, \zeta_0)$, $\theta(\omega_k, \omega_{k+1}, \omega_0, \zeta_0)$, and $\psi(\omega_k, \omega_{k+1}, \omega_0, \zeta_0)$ are determined in closed form.

In the scenario of iterative methods to define the power-spectral density function from a known response spectrum, Pfaffinger (1983) proposed a procedure in which a discretization by piecewise polynomials is numerically implemented. The free parameters are determined iteratively by a least squares fit. The peak factor used the

expression provided by Davenport (1964), assuming the statistical independence of outcrossing of a given barrier, that is,

$$\eta_U = \sqrt{2 \ln(2N_U)} + \frac{\gamma}{\sqrt{2 \ln(2N_U)}} \quad (36)$$

where $\gamma = 0.5772$ is the Euler constant and N_U is given by Eq. 15.

The unilateral spectrum-compatible power-spectral density function is discretized in the interval $\omega_k < \omega < \omega_{k+1}$ and obtained by summation of the piecewise polynomials as follows:

$$G(\omega) = \sum_{k=1}^N p_k P_k(\omega) \quad k = 1, \dots, N \quad (37)$$

where p_i are either free parameters or have to be assigned to satisfy specified conditions and $P_i(\omega)$ are the interpolation polynomials.

According to the approximation given Eq. 37, the standard deviation and mean outcrossing rate of the zero level are obtained from the following equations, respectively:

$$\sigma_U = \left(\sum_{i=1}^N p_i I_{0,i}(\omega_0, \zeta_0) \right)^{1/2} \quad (38)$$

and

$$v_U = \frac{1}{2\pi} \left[\frac{\sum_{i=1}^N p_i I_{2,i}(\omega_0, \zeta_0)}{\sum_{i=1}^N p_i I_{0,i}(\omega_0, \zeta_0)} \right]^{1/2} \quad (39)$$

where $I_{2j,i}$ is given by

$$I_{2j,i}(\omega_0, \zeta_0) = \int_{\omega_k}^{\omega_{k+1}} \frac{\omega^{2j} P_k(\omega)}{(\omega_0^2 - \omega^2)^2 + 4\zeta_0^2 \omega_0^2 \omega^2} d\omega \quad j = 0, 1 \quad (40)$$

That has been derived analytically. The parameters p_i and the polynomial coefficients are finally determined through a least squares fitting.

Based on the iterative model proposed by Pfaffinger (1983), Park (1995) defined a method

to derive the equivalent power-spectral density function from a given target response spectrum.

The approach to the modeling consists of assuming the bilateral power-spectral density function as the summation of Dirac's delta functions with unknown amplitudes, that is,

$$S(\omega) = \sum_{j=1}^m S(\omega_j) \Delta\omega_j \delta(\omega_j) = \sum_{j=1}^m p_j \delta(\omega_j) \quad (41)$$

where $S(\omega)$ is the unknown two-sided power-spectral density function, $\delta(\omega_j)$ are Dirac's delta functions for each component, $\Delta\omega_j$ is the incremental frequency step, and p_j are the discretized power components.

Therefore by superimposing a series of Dirac's delta functions which may represent a narrowband process, the result will be a wide-band process as the real earthquake frequency content characterization.

The discretized target response spectrum is obtained as a superposition of the components of the power and of the response spectrum in itself as follows:

$$RSA^2(\omega_k, \zeta_0) = \sum_{j=1}^m p_j RSA_{k,j}^2(\omega_k, \omega_j, \zeta_0) \quad \text{for } k = 1, 2, \dots, m \quad (42)$$

where $RSA(\omega_k, \zeta_0)$ is the discretized target response spectrum and $RSA_{k,j}(\omega_k, \omega_j, \zeta_0)$ is the

peak acceleration response of a single degree of freedom system with natural frequency ω_k , damping ratio ζ_0 , and forced by the narrowband $\delta(\omega_j)$ Dirac's delta functions. $RSA_{k,j}(\omega_k, \omega_j, \zeta_0)$ is determined using the peak factor approximation by Davenport (1964) with N_U given by Eq. 15 and equivalent duration T_e defined as

$$T_e = \frac{\int_0^{t_f} a(t) dt}{\max[a(t)]} \quad (43)$$

where $a(t)$ is a selected time-modulating function and t_f is the total duration of the earthquake.

The unknown coefficients p_j defining the power-spectral density function are evaluated by minimizing the following penalty function:

$$\sum_{k=1}^n \left[RSA^2(\omega_k, \zeta_0) - \sum_{j=1}^m p_j RSA_{k,j}^2(\omega_k, \omega_j, \zeta_0) \right]^2 \quad p_j \geq 0; \quad (44)$$

where n represents the number of frequencies discretizing the target response spectrum.

Following the direct approach proposed by Vanmarcke and Gasparini (1977), Cacciola et al. (2004) developed a handy and accurate recursive expression for determining the spectrum-compatible power-spectral density function as follows:

$$G(\omega_i) = 0, \quad \forall 0 \leq \omega \leq \omega_x$$

$$G(\omega_i) = \frac{4\zeta_0}{\omega_i \pi - 4\zeta_0 \omega_{i-1}} \left(\frac{RSA(\omega_i, \zeta_0)^2}{\eta_U^2(\omega_i, \zeta_0)} - \Delta\omega \sum_{k=1}^{i-1} G(\omega_k) \right), \quad \forall \omega > \omega_x \quad (45)$$

where $\omega_x \cong 1 \text{ rad/s}$ is the lowest bound of the existence domain of then peak factor and η_U is the peak factor evaluated according to Vanmarcke

(1972) for white noise input (and $p = 0.5$) here rewritten for clarity's sake

$$\eta_U(\omega_0, \zeta_0) = \sqrt{2 \ln \left\{ \frac{\omega_0 T_s}{\pi(-\ln p)} \left[1 - \exp \left[-\delta_U^{1.2} \sqrt{\pi \ln \left(\frac{\omega_0 T_s}{\pi(-\ln p)} \right)} \right] \right] \right\}} \quad (46)$$

and spread factor (Vanmarke 1976)

$$\delta_U = \left[1 - \frac{1}{1 - \zeta_0^2} \left(1 - \frac{2}{\pi} \arctan \frac{\zeta_0}{\sqrt{1 - \zeta_0^2}} \right)^2 \right]^{\frac{1}{2}} \quad (47)$$

Recently Di Paola and Navarra (2009) proposed a closed form expression for the spectrum compatible power-spectral density function which parameters were defined through a best fitting of the model proposed by Cacciola et al. (2004).

Numerical Application

The direct models described are herein applied to simulate artificial quasi-stationary accelerograms compatible with a given response spectrum. Specifically, Eq. 7 in conjunction with Eq. 2 is used to generate the ground motion time histories.

Jennings et al. (1969) time-modulating function presented in Eq. 6 is used for this purpose. In this application the values of the parameters t_1 , t_2 , and β_4 are evaluated by imposing that the energy of the stochastic ground motion reaches the values of the 5 % and 95 %, respectively, in t_1 and t_2 , namely, by the use of the generalized Husid function extended for stochastic processes as proposed by Cacciola and Deodatis (2011)

$$H(t) = \frac{\int_0^t \int_0^\infty a^2(\tau) G(\omega) d\omega d\tau}{\int_0^\infty \int_0^\infty a^2(\tau) G(\omega) d\omega d\tau} \quad (48)$$

and imposing that $H(t_1) = 0.05$ and $H(t_2) = 0.95$, Eq. 47 leads to the following analytical values of Jennings's parameters as function of the duration of the stationary part T_s , that is,

$$\beta_4 = \frac{9}{T_s}; t_1 = \frac{2.5}{\beta_4}; t_2 = \frac{11.5}{\beta_4} \quad (49)$$

The stationary power-spectral density function in Eq. 48 is determined according to the direct procedures proposed by Gasparini and Vanmarke

(1976), Vanmarcke and Gasparini (1977), Kaul (1978), Preumont (1980), Der Kiureghian and Neuenhofer (1992), and Cacciola et al. (2004).

The Eurocode 8 response spectrum is used for illustrative purpose; specifically for a 5 % damping ratio, the response spectrum is given by the following equations:

$$\begin{aligned} RSA(T_0) &= a_g S \left[1 + \frac{T_0}{T_B} (1.5) \right] & 0 \leq T_0 \leq T_B \\ RSA(T_0) &= 2.5 a_g S & T_B \leq T_0 \leq T_C \\ RSA(T_0) &= 2.5 a_g S \left[\frac{T_C}{T_0} \right] & T_C \leq T_0 \leq T_D \\ RSA(T_0) &= 2.5 a_g S \left[\frac{T_C T_D}{T_0^2} \right] & T_D \leq T_0 \leq 4s \end{aligned} \quad (50)$$

where a_g is the design ground acceleration, S is the soil factor, T_0 is the natural period, and T_B , T_C , and T_D are the periods specified relatively to the soil type.

According to the Eurocode 8 provisions, the mean response spectrum of the simulated time histories has to match the target response spectrum within the prescribed tolerance along the prefixed range of periods according to the following condition:

$$\max \left\{ \frac{RSA(T_0) - \overline{RSA}(T_0)}{RSA(T_0)} \times 100 \right\} \leq 10\% \quad (51)$$

where $\overline{RSA}(T_0)$ is the mean response spectrum of at least three simulated accelerograms and $RSA(T_0)$ is the target one: moreover it has to be verified that

$$\overline{RSA}(0) > a_g S \quad (52)$$

The parameters chosen in this numerical application correspond to the ground Type A, namely, $S = 1$, $T_B = 0.1$ s, $T_C = 0.4$ s, $T_D = 2.0$ s; the maximum ground acceleration set is $a_g = 1$ m/s². Furthermore according to the Eurocode 8, the duration of the stationary part has to be taken at least of 10 s. Therefore the strong motion of Jennings's modulating function is set equal to $T_s = 10$ s

Response-Spectrum-Compatible Ground Motion Processes,

Fig. 1 Comparison between the power-spectral density functions

Response-Spectrum-Compatible Ground Motion Processes,

Fig. 2 Comparison between different peak factor's definitions adopted in the compared models

Figure 1 shows the power-spectral density functions according to the selected models which were numerically evaluated assuming the frequency step of 0.1 rad/s. Slight differences are noticeable between all the models apart from Der Kiureghian and Neuenhofer (1992) and Kaul (1978); all the other power-spectral density functions tend to similar values outside a certain range

of frequencies, in which the amplitude of the functions tends to negligibility.

Figure 2 elucidates the influence of assuming a constant value for the peak factor. The closed form expression given in the Eurocode 8 part 2, in which the peak factor is considered equal to 2.5, maintains considerable higher energy content compared with the others. From Fig. 2

Response-Spectrum-Compatible Ground Motion Processes,

Fig. 3 Comparison of the mean ensemble of the simulated response spectra

it can be observed that the constant value 2.5 is quite below the other peak factors in the range between 10 and 100 rad/s. Therefore the power-spectral density function is clearly overestimated by the function proposed in Eurocode 8 for $T_s = 10$ s.

Note that the peak factor relative to the model of Kaul (1978) is identical to the peak factor presented for Vanmarcke and Gasparini (1977); hence in Fig. 2, its variation with the frequency is not mentioned.

Successively 100 samples of accelerograms have been generated via superposition of harmonics through Eq. 7 using a time sampling step of 0.01 s and of 0.1 rad/s for the frequency domain. The time histories were generated in order to evaluate the mean of the ensemble of the simulated response spectra as shown in Fig. 3.

From Fig. 3 it is observed that the model proposed by Eurocode 8 leads to a mean simulated response spectrum quite above the recommended one; however it is spectrum compatible as it fulfils the conditions Eqs. 50 and 51.

No iteration has been adopted in order to improve the matching between the prescribed response spectrum and the mean-simulated stochastic response spectral accelerations, which

generally can be pursued by the following iterative scheme:

$$\begin{aligned} G_0^{(1)}(\omega_0) &= G_0(\omega_0); \quad G_0^{(j)}(\omega_0) \\ &= G_0^{(j-1)}(\omega_0) \left[\frac{RSA(\omega_0, \zeta_0)}{RSA^{(j-1)}(\omega_0, \zeta_0)} \right]^2 \end{aligned} \quad (53)$$

where $RSA^{(j-1)}$ is the approximate pseudo-acceleration spectrum determined at the j th iteration and RSA is the target response spectrum.

Nonstationary Models

In the previous sections the most common procedures to determine stationary/quasi-stationary power-spectral density functions compatible with a given response spectrum have been presented. It should be noted at the outset that the ground motion time histories generated from quasi-stationary stochastic processes have energy content only variable with time. Although this approach is convenient and accurate for the seismic analysis of traditional linear behaving structures, it does not lead to a comprehensive description of the seismic phenomenon.

It must be highlighted that the variation of the frequency content of stochastic ground motions has been recognized of primary importance in the seismic assessment of relevant engineering structures (see e.g., Yeh and Wen 1990; Wang et al. 2002); therefore the influence of the amplitude and the frequency time variation should be equally hypothesized to feature more realistically the structural response to earthquake ground motions.

Problem Position

Assuming the ground acceleration process as zero-mean Gaussian nonstationary non-separable

process, the evaluation of spectrum-compatible power-spectral density functions could be undertaken by the “first passage problem” pursued for the nonstationary case (Corotis et al. 1972; Cacciola 2011), that is,

$$\exp \left[- \int_0^{t_f} \alpha_U(RSA(\omega_0, \zeta_0), t) dt \right] = p \quad (54)$$

where t_f is the time interval in which the ground motion possesses not negligible energy and α_U is the hazard function defined as

$$\alpha_U(RSA(\omega_0, \zeta_0), t) = \frac{1}{\pi} \sqrt{\frac{\lambda_{2,U}(t)}{\lambda_{0,U}(t)}} \frac{1 - \exp \left(- \sqrt{\frac{\pi}{2}} \frac{RSA(\omega_0, \zeta_0)/\omega_0^2}{\sqrt{\lambda_{0,U}(t)}} \delta_U(t) \right)}{\exp \left(\frac{(RSA(\omega_0, \zeta_0)/\omega_0^2)^2}{2\lambda_{0,U}(t)} \right) - 1} \quad (55)$$

where the time-varying spread factor is given by

$$\delta_U(t) = \sqrt{1 - \frac{\lambda_{1,U}^2(t)}{\lambda_{0,U}(t)\lambda_{2,U}(t)}} \quad (56)$$

where $\lambda_{i,U}(t)$ ($i = 0, 1, 2$) represent the nonstationary spectral moments of the response (see e.g., Mikealov et al. 1999).

Ideally by Eqs. 54, 55, and 56 and the definition of the nonstationary spectral moments of the response, the evolutionary power-spectral density function pertinent to the codes prescriptions could be derivable. However this approach not yet attempted, to the best knowledge of the authors, it could be computationally burdensome, the convergence is not assured, and moreover it may lead to physically unacceptable results; therefore alternative approaches are usually preferred.

In the framework of Gaussian spectrum compatible nonstationary ground motion models, very few procedures have been proposed in literature. Herein the ground motion models developed by Spanos and Vargas Loli (1985),

Preumont (1985), and Cacciola (2010) are described; moreover the explicit formulae among those proposed are compared in a numerical application.

State of the Art for Available Solutions

Spanos and Vargas Loli (1985) for the first time developed the relationship between the evolutionary power-spectral density function and a known response spectrum. The authors defined an approximate analytical expression whose parameters were derived from an optimization procedure.

In order to determine the link between the power-spectral density function and the target response spectrum, the authors derived the following relationship:

$$RSV(\omega_0, \zeta_0) = r\sigma_{U_{\max}}^2(\omega_0, \zeta_0) \quad (57)$$

where $RSV(\omega_0, \zeta_0)$ is the velocity target response spectrum, $\sigma_{U_{\max}}$ is the maximum of the variance of the response velocity, and r is a scaling factor which value is taken equal to $\sqrt{\pi/2}$.

The variance of the velocity response process is approximated by the authors by

$$\begin{aligned}\sigma_{\dot{U}}^2(t) &\approx \omega_0^2 \sigma_U^2(t) \\ &= \pi \exp(-2\zeta_0 \omega_0 t) \int_0^t \exp(2\zeta_0 \omega_0 t) S(\omega, t) dt\end{aligned}\quad (58)$$

where $S(\omega, t)$ is the bilateral power-spectral density function to be determined. In order to determine the power-spectral density function from Eq. 56, the authors assumed the evolutionary power spectrum as a linear combination of m separable functions through the following mathematical model:

$$S(\omega, t) = \sum_{k=1}^m C_k t^2 \exp(-\alpha_k t) S_k(\omega) \quad (59)$$

$S_k(\omega)$ is the Kanai-Tajimi power-spectral density function

$$S_k(\omega) = \frac{1 + 4\zeta_k^2 \left(\frac{\omega_0}{\omega_k}\right)^2}{\left\{1 - \left(\frac{\omega_0}{\omega_k}\right)^2\right\}^2 + 4\zeta_k^2 \left(\frac{\omega_0}{\omega_k}\right)^2} \quad (60)$$

where ω_k and ζ_k , which are respectively the natural frequency and the damping ratio of the single degree of freedom system representing the soil, are parameters to be determined along with C_k and α_k in Eq. 58.

By substituting Eq. 58 into Eq. 57, the maximum of $\sigma_{\dot{U}}^2(t)$ is given by

$$\sigma_{\dot{U}_{\max}}^2 = \frac{\pi}{2\zeta_0 \omega_0} \sum_{k=1}^m C_k t^{*2} \exp(-\alpha_k t^*) S_k(\omega_0) \quad (61)$$

Therefore by means of Eqs. 60 and 56, the relationship between the velocity target response spectrum and the modeled evolutionary power-spectral density function is expressed by the equation

$$RSV^2(\omega_0, \zeta_0) = r^2 \frac{\pi}{2\zeta_0 \omega_0} \sum_{k=1}^m C_k t^{*2} \exp(-\alpha_k t^*) S_k(\omega_0) \quad (62)$$

The differences between the target spectrum on the left-hand side and the right-hand side of the above formula are minimized through the Levenberg-Marquardt procedure by best fitting of the constant parameters $t_1^*, t_2^*, \dots, t_n^*, C_k, \alpha_k, \zeta_k, \omega_k$.

After defining the evolutionary power-spectral density function samples of ground motion process are generated by Eq. 7. An iterative procedure is successively required in order to ensure the matching of the simulated and target response spectra (Giaralis and Spanos 2009).

In the same year, the relevance of the nonstationarity of the frequency content in the modeling of the ground motion has been highlighted by Preumont (1985); the author defined an empirical model of the non-separable power-spectral density function. The model assumes that the high-frequency components are magnified in the early part of the time history. Specifically, the following evolutionary spectrum is assumed

$$G(\omega, t) = t^2 e^{-\alpha(\omega)t} G(\omega) \quad (63)$$

with

$$\alpha(\omega) = \alpha_0 + \alpha_1 \omega + \alpha_2 \omega^2 \quad (64)$$

where α_0 , α_1 , and α_2 are adjustable parameters calibrated to impose the equation between the energy of the separable and non-separable process.

The matching of the mean simulated and target response spectra is ensured by equating at each frequency the energy of the separable spectrum-compatible process and that one of the non-separable, that is,

$$G^S(\omega) \int_0^\infty a(t)^2 dt = G(\omega) \int_0^\infty t^2 e^{-\alpha(\omega)t} dt = G(\omega) \frac{2}{\alpha(\omega)^3} \quad (65)$$

where $G^S(\omega)$ is the stationary response-spectrum-compatible power-spectral density function determined according to the procedures described in the previous sections and $a(t)$ is the time-modulating function (see e.g., Eq. 6)

Therefore through Eq. 64 $G(\omega)$ in Eq. 62 is readily determined as follows:

$$G(\omega) = \frac{\int_0^\infty a^2(t) dt}{\int_0^\infty t^2 e^{-\alpha(\omega)t} dt} G^S(\omega) = \frac{\alpha(\omega)^3}{2} G^S(\omega) \int_0^\infty a^2(t) dt \quad (66)$$

Once $a(t)$ is defined, the evolutionary power-spectral density function is pursued by means of Eqs. 62 and 63 in which the coefficients α_0 , α_1 , and α_2 are suitably determined.

An alternative approach has been proposed by Cacciola (2010); the author's contribution allows a straightforward evaluation of a non-separable power-spectral density function compatible with a target response spectrum. In the model proposed by Cacciola (2010), it is assumed that the nonstationary spectrum-compatible evolutionary ground motion process is given by the superposition of two independent contributions: the first one is a fully nonstationary known counterpart which accounts for the time variability of both intensity and frequency content; the second one is a corrective term represented by a quasi-stationary zero-mean Gaussian process that adjusts the nonstationary signal in order to make it spectrum compatible. Therefore the ground motion can be split in two contributions:

$$\ddot{u}_g(t) = \ddot{u}_g^R(t) + \ddot{u}_g^C(t) \quad (67)$$

Taking into account of the statistical independence of the two contributions, the evolutionary spectrum-compatible power-spectral density function can be expressed as

$$G(\omega, t) = G^R(\omega, t) + G^C(\omega, t) \quad (68)$$

where $G^R(\omega, t)$ is the joint time-frequency distribution of the recorded accelerogram and $G^C(\omega, t)$

is the separable power-spectral density function representing of the corrective term given by

$$G^C(\omega, t) = a^2(t)G(\omega) \quad (69)$$

Specifically $G^R(\omega, t)$ is attained by the fully nonstationary model of Conte and Peng (1997), which hypothesizes the stochastic ground motion as a series of zero-mean independent uniformly modulated Gaussian processes as

$$G(\omega, t) = \sum_{j=1}^N |a_j(t)|^2 G_j(\omega) \quad (70)$$

where

$$a_j(t) = \alpha_j(t - \vartheta_j)^{\beta_j} \exp(-\gamma_j(t - \vartheta_j)) U(t - \vartheta_j) \\ j = 1, \dots, N \quad (71)$$

where $U(t - \vartheta_j)$ is the unit step function and $G_j(\omega)$ a stationary counterpart obtained as

$$G_j(\omega) = \frac{v_j}{\pi} \left[\frac{1}{v_j^2 + (\omega + \eta_j)^2} + \frac{1}{v_j^2 + (\omega - \eta_j)^2} \right] \\ j = 1, \dots, N \quad (72)$$

in which the parameters N , α_j , β_j , γ_j , ϑ_j , η_j , v_j are determined by a best fit procedure in order to minimize the differences between the analytical model and the joint time-frequency distribution of a real earthquake.

In order to define the corrective term $G^C(\omega, t)$ according to the quasi-stationary model described in the previous section, $a(t)$ is the modulating function given in Eq. 6 whose parameters are calibrated by the knowledge of the recorded accelerograms and $G(\omega)$ is determined modifying Eq. 45 as follows:

$$G^C(\omega_i) = \begin{cases} 0, & 0 \leq \omega \leq \omega_x \\ \frac{4\zeta_0}{\omega_i \pi - 4\zeta_0 \omega_{i-1}} \left(\frac{RSA(\omega_i, \zeta_0)^2 - RSA^R(\omega_i, \zeta_0)^2}{\eta_U^2(\omega_i, \zeta_0)} - \Delta \omega \sum_{k=1}^{i-1} G^C(\omega_k) \right), & \omega > \omega_x \end{cases} \quad (73)$$

where η_U is the peak factor defined in Eq. 19 and RSA^R is the pseudo-acceleration response spectrum for the recorded ground motions $\ddot{u}_g^R(t)$. Equation 72 is defined for $RSA(\omega_i, \zeta_0) > RSA^R(\omega_i, \zeta_0)$, as a consequence a preliminary scaling procedure might be required.

It has to be emphasized that due to the mathematical structure of the model proposed by Conte and Peng (1997), Eq. 67 can be rewritten in the form

$$\begin{aligned} G(\omega, t) &= G^R(\omega, t) + G^C(\omega, t) \\ &= \sum_{j=1}^N |a_j(t)|^2 G_j(\omega) + a_0^2(t) G(\omega) \\ &= \sum_{j=0}^N |a_j(t)|^2 G_j(\omega) \end{aligned} \quad (74)$$

which allows a compact representation of the evolutionary spectrum-compatible power-spectral density function. It is noted that in the formulation proposed by Cacciola (2010), the nonstationary frequency content is not modeled through empirical analytical formulas, but it is selected from real records.

Numerical Application

In this section the ground motion stochastic processes modeled according to Preumont (1985) and Cacciola (2010) are presented through a numerical example. The models have been selected as those holding an explicit formulation of the evolutionary power-spectral density function among those herein presented.

The spectrum-compatibility of the two procedures is illustrated considering a given target response spectrum as prescribed by Eurocode 8 and expressed in Eq. 50. The response spectrum for Type B soil and Type 1 seismicity is selected; the parameters corresponding to the recommended spectrum are, namely, $S = 1.2$, $T_B = 0.15$ s, $T_C = 0.5$ s, $T_D = 2.0$ s and the design ground acceleration was set equal to 0.35 g.

To implement the model proposed by Preumont (1985), the values relatively to the time-modulating function seen in Eqs. 62 and 63

were set respectively equal to $\alpha_0 = 0.3$, $\alpha_1 = 0.01$, and $\alpha_2 = 0$. Also, the time-modulating function is selected according to the author preferences; hence Jennings et al.'s (1969) envelope function was taken for a strong motion of $T_s = 13$ s, $t_1 = 2$ s, $t_2 = 15$ s, and total duration $t_f = 20$ s.

In order to apply the procedure proposed by Cacciola (2010), firstly the evolutionary power spectrum as developed by Conte and Peng (1997) is obtained specifically for El Centro 1940 earthquake, north-south component SOOE (N-S) of the Imperial Valley.

Jennings et al.'s (1969) model is chosen also for this model as in Eq. 6. The parameters for the time-modulating function are defined according to the real strong motion quantified as $T_s = 23.86$ s, namely, these are $t_1 = 1.65$ s, $t_2 = 25.51$ s total duration $t_f = 31$ s and parameter $\beta_4 = 3/(t_f - t_2)$. Finally to evaluate the simulated response spectra a number of 100 time histories were generated via Monte Carlo simulation method by Eq. 7.

The evolutionary power-spectral density functions proposed by the authors are displayed in Fig. 4a, b; in general, due to the nonstationarity and the approximations involved in the models, the iterative scheme as seen in Eq. 52 is required. Therefore Fig. 4c, d shows the iterated power-spectral density functions; markedly it should be observed that although the different joint time-frequency distribution both the models can be used according to the seismic provisions for simulating ground motion accelerograms and evidently tending to reach the spectrum-compatibility criteria as shown in Fig. 5.

Figure 5 displays that both the models reached the required spectrum-compatibility after the contained number of 5 iterations over the recommended range of period.

Nonstationary Vector Processes

Ground motion arising from seismic waves is a phenomenon that by its nature varies with time and in space. Even if, in earthquake engineering

Response-Spectrum-Compatible Ground Motion Processes, Fig. 4 Evolutionary power-spectral density functions according to (a) Preumont (1985); (b) Preumont

(1985) after 5 iterations; (c) Cacciola (2010); (d) Cacciola (2010) after 5 iterations

practice, the attention is generally focused on the time variability feature and its effects on the structural response; on the other hand, it is well known that the spatial variability of earthquake ground motion can influence significantly the response of structures, especially if they are long and/or rigid such as bridges and nuclear power plants. Zerva (2009) presents an overview of the engineering applications in which ground motion spatial variability has been taken into account and for an in-depth discussion of the state of the art along with the challenges

involved in modeling the spatial variability of earthquake ground motion. The spatial variability of the earthquake ground motion can be modeled assuming the hypothesis of a zero-mean Gaussian multivariate vector process. Following the spectral-representation method proposed by Shinozuka and Deodatis (1988), assuming the 1D- m V (one-dimensional, m -variate), the nonstationary ground motion stochastic vector process with components $f_j^0(t)$, ($j = 1, \dots, m$) is defined by the cross-correlation matrix given by

Response-Spectrum-Compatible Ground Motion Processes,

Fig. 5 Comparison of the ensemble of the simulated response spectra before and after 5 iterations

$$\mathbf{R}_f^0(t, t + \tau) = \begin{bmatrix} R_{11}^0(t, t + \tau) & R_{12}^0(t, t + \tau) & \cdots & R_{1m}^0(t, t + \tau) \\ R_{21}^0(t, t + \tau) & R_{22}^0(t, t + \tau) & \cdots & R_{2m}^0(t, t + \tau) \\ \vdots & \vdots & \ddots & \vdots \\ R_{m1}^0(t, t + \tau) & R_{m2}^0(t, t + \tau) & \cdots & R_{mm}^0(t, t + \tau) \end{bmatrix} \quad (75)$$

$$\mathbf{S}_f^0(\omega, t) = \begin{bmatrix} S_{11}^0(\omega, t) & S_{12}^0(\omega, t) & \cdots & S_{1m}^0(\omega, t) \\ S_{21}^0(\omega, t) & S_{22}^0(\omega, t) & \cdots & S_{2m}^0(\omega, t) \\ \vdots & \vdots & \ddots & \vdots \\ S_{m1}^0(\omega, t) & S_{m2}^0(\omega, t) & \cdots & S_{mm}^0(\omega, t) \end{bmatrix} \quad (76)$$

Or alternatively by the corresponding cross-spectral density matrix given by

whose elements are expressed in the following form:

$$\begin{aligned} S_{jj}^0(\omega, t) &= |a_j(\omega, t)|^2 S_j(\omega), & j &= 1, 2, \dots, m \\ S_{jk}^0(\omega, t) &= a_j(\omega, t) a_k(\omega, t) \sqrt{S_j(\omega) S_k(\omega)} \gamma_{jk}(\omega), & j, k &= 1, 2, \dots, m; \quad j \neq k \end{aligned} \quad (77)$$

where $a_j(\omega, t)$ and $S_j(\omega)$ ($j = 1, 2, \dots, m$) are the (non-separable) modulating function and the (stationary) power-spectral density function of component $f_j^0(t)$, ($j = 1, 2, \dots, m$), respectively, and $\gamma_{jk}(\omega)$ ($j, k = 1, 2, \dots, m; j \neq k$) is the complex coherence function between $f_j^0(t)$ and $f_k^0(t)$. The elements of the cross-correlation matrix are related to the corresponding elements of the cross-spectral density matrix through the transformations:

$$R_{jj}^0(t, t + \tau) = \int_{-\infty}^{\infty} a_j(\omega, t) a_j(\omega, t + \tau) S_j(\omega) e^{i\omega\tau} d\omega; \quad j = 1, 2, \dots, m \quad (78)$$

$$\begin{aligned} R_{jk}^0(t, t + \tau) &= \int_{-\infty}^{\infty} a_j(\omega, t) a_k(\omega, t + \tau) \\ &\quad \sqrt{S_j(\omega) S_k(\omega)} \gamma_{jk}(\omega) e^{i\omega\tau} d\omega; \\ &\quad j, k = 1, 2, \dots, m; \quad j \neq k \end{aligned} \quad (79)$$

For the special case of uniformly modulated nonstationary stochastic vector process, the modulating functions $a_j(\omega, t)$ ($j = 1, 2, \dots, m$) are independent of the frequency ω , that is,

$$a_j(\omega, t) = a_j(t), \quad j = 1, 2, \dots, m \quad (80)$$

In this case, Eqs. 77 and 78 reduce to

$$R_{jj}^0(t, t + \tau) = a_j(t)a_j(t + \tau) \int_{-\infty}^{\infty} S_j(\omega)e^{i\omega\tau}d\omega; \quad j = 1, 2, \dots, m \quad (81)$$

$$R_{jk}^0(t, t + \tau) = a_j(t)a_k(t + \tau) \int_{-\infty}^{\infty} \sqrt{S_j(\omega)S_k(\omega)}\gamma_{jk}(\omega)e^{i\omega\tau}d\omega; \quad j, k = 1, 2, \dots, m; j \neq k \quad (82)$$

After determining the power-spectral density matrix samples of 1D- m -variate ground motion process can be determinate (Deodatis 1996). Specifically, Cholesky's decomposition is applied to decompose the power spectra density matrix as follows:

$$\mathbf{S}_f^0(\omega, t) = \mathbf{H}(\omega, t)\mathbf{H}^{T*}(\omega, t) \quad (83)$$

where $\mathbf{H}(\omega, t)$ is a lower triangular matrix and the superscript T denotes the transpose of a matrix. $\mathbf{H}(\omega, t)$ is written as

$$\mathbf{H}(\omega, t) = \begin{bmatrix} H_{11}(\omega, t) & 0 & \cdots & 0 \\ H_{21}(\omega, t) & H_{22}(\omega, t) & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ H_{m1}(\omega, t) & H_{m2}(\omega, t) & \cdots & H_{mm}(\omega, t) \end{bmatrix} \quad (84)$$

The diagonal elements of $\mathbf{H}(\omega, t)$ are real and nonnegative functions of ω satisfying

$$H_{jj}(\omega, t) = H_{jj}(-\omega, t), \quad j = 1, 2, \dots, m; \quad \forall t \quad (85)$$

while the off-diagonal elements are generally complex functions of ω . Once the cross-spectral density matrix $\mathbf{S}_f^0(\omega, t)$ is decomposed according to Eq. 82 and 83, the nonstationary ground motion vector process $f_j^0(t)$, $j = 1, 2, \dots, m$ can be simulated by the following series as $N \rightarrow \infty$

$$f_j(t) = 2 \sum_{r=1}^m \sum_{s=1}^N |H_{jr}(\omega_s, t)| \sqrt{\Delta\omega} \cos [\omega_s t - \vartheta_{jr}(\omega_s, t) + \phi_{rs}], \quad j = 1, 2, \dots, m \quad (86)$$

Or explicitly

$$f_1(t) = 2 \sum_{s=1}^N |H_{11}(\omega_s, t)| \sqrt{\Delta\omega} \cos [\omega_s t - \vartheta_{11}(\omega_s, t) + \phi_{1s}] \quad (87)$$

$$f_2(t) = 2 \sum_{s=1}^N |H_{21}(\omega_s, t)| \sqrt{\Delta\omega} \cos [\omega_s t - \vartheta_{21}(\omega_s, t) + \phi_{1s}] + 2 \sum_{s=1}^N |H_{22}(\omega_s, t)| \sqrt{\Delta\omega} \cos [\omega_s t - \vartheta_{22}(\omega_s, t) + \phi_{2s}] \quad (88)$$

where

$$\vartheta_{jk}(\omega, t) = \tan^{-1} \left(\frac{\text{Im}[H_{jk}(\omega, t)]}{\text{Re}[H_{jk}(\omega, t)]} \right) \quad (89)$$

with $\text{Im}[\cdot]$ and $\text{Re}[\cdot]$ denoting the imaginary and real part of a complex number, respectively. Furthermore, the ϕ_{rs} ($r = 1, 2, \dots, m$; $s = 1, 2, \dots, N$) are m sequences of N independent random phase angles distributed uniformly over the interval $[0, 2\pi)$.

Clearly, the proper definition of the power-spectral density matrix is the crucial step to address for the stochastic modeling of the

seismic action. In this regard the challenge is to simulate artificial accelerograms, that are compatible with response spectra defined in different locations and correlated through the coherence function $\gamma_{jk}(\omega)$ introduced in Eq. 76. The definition of the coherence function is still an open issue in the scientific community. The readers might refer to the monograph of Zerva (2009) for a detailed description of coherence functions.

Based on the data provided from the main Strong Motion Array Taiwan (SMART-1), Hao et al. (1989) developed a method for generating stationary and quasi-stationary multi-support inputs for any given set of location which are compatible with target response spectra. To this aim a coherence function is developed for pairs of stations, that is,

$$\begin{aligned} \gamma_{ij}(d_{ij}^L, d_{ij}^T, \omega) = & \exp(-b_1 d_{ij}^L - b_2 d_{ij}^T) \\ & \exp\left[-\left(-a_1 d_{ij}^{L1/2} + a_2 d_{ij}^{T1/2}\right)\omega^2\right] \\ & \exp\left(i\omega \frac{d_{ij}^L}{v_{app}}\right) \end{aligned} \quad (90)$$

where d_{ij}^L, d_{ij}^T are the station pairs distances with same projected separation in the longitudinal and transverse direction of the preferential wave propagation, ω is the circular frequency, v_{app} is the apparent wave velocity, the parameters a_1, a_2, b_1 , and b_2 were evaluated by least squares fitting using SMART-1 data.

The averaged power-spectral density function $S_k(\omega)$ for all the stations was calculated by best fitting the Kanai-Tajimi model. Finally, the modulating function amplitude variation was evaluated assuming the following model:

$$a(t) = \delta t \exp(-\beta_5 t^2) \quad (91)$$

whose parameters are determined through best-fitting procedures. Once defined the elements of the power-spectral density matrix, the simulation of quasi-stationary vector process is pursued through a specific algorithm. The matching with the target response spectrum is guaranteed through an iterative procedure, scaling the

Fourier transform of the generated accelerograms through the ratio of the target and simulated response spectra and then determining the spectrum-compatible ground motion acceleration through the inverse Fourier transform.

Deodatis (1996) proposed a general iterative procedure to determine quasi-stationary response-spectrum-compatible ground motion vector process. The procedure requires the initial selection of the modulating functions and coherence functions representative of a given site. The procedure starts assuming the stationary power-spectral density function constant for every location:

$$S_j(\omega, t) = a^2(t) S_j(\omega) \quad (92)$$

where $a(t)$ is the time-modulating function and $S_j(\omega)$ the stationary power-spectral density function.

The problem solution starts assuming a constant value $S_j(\omega)$ at each frequency.

The ground motion accelerograms at each point on the free field are then simulated according to the spectral-representation method described in Eqs. 76, 77, 78, 79, and 80 and 83, 84, 85, 86, 87, 88, and 89. The matching is guaranteed by updating individually each power-spectral density functions $S_j(\omega)$ according to the iterative scheme described in Eq. 52.

By using a wavelet-based approach, a method to define fully nonstationary spectrum-compatible vector processes has been introduced by Sarkar and Gupta (2005). The proposed scheme assumes that a suitable accelerogram conforming to the local source and site conditions is available. The procedure is developed assuming that each point at the free field possess the same response spectrum. The accelerogram is first modified to make it spectrum compatible to the target response spectrum through a deterministic iterative procedure. The power-spectral density function from the response-spectrum-compatible accelerogram at a given time instant is determined as

$$S_X(\omega_j) = \frac{K}{a_j} E \left[|W_{\psi} X(a_j, b_j)|^2 \right] \left| \hat{\psi}_{a_j, b_j}(\omega_j) \right|^2 \quad (93)$$

where $W_{\psi}X(a_j, b_j)$ is the wavelet coefficient for the response-spectrum-compatible accelerogram at scale parameter a_j and shift parameter $b_j = (i - 1)\Delta b$ in which Δb is the sampling time interval of the accelerogram, K is a scaling coefficient, and $\hat{\psi}_{a_j, b_j}(\omega_j)$ is the Fourier transform of $\psi_{a_j, b_j}(t_j)$ defined from the mother wavelet.

The off-diagonal terms in Eq. 76 are determined imposing a coherence function. The simulation of m -variate response-spectrum-compatible accelerograms is then performed extending the spectral-representation method described in Eqs. 76, 77, 78, 79, and 80 and 83, 84, 85, 86, 87, 88, and 89 to a wavelet simulation-based procedure.

Recently, the procedure developed by Deodatis (1996) for quasi-stationary response-spectrum-compatible vector process has been extended by Cacciola and Deodatis (2011) to the fully nonstationary case. According to the model introduced by Cacciola (2010), the authors proposed a response-spectrum-compatible ground motion model given by the superposition of two contributions:

$$f_j^{SC}(t) = f_j^L(t) + f_j^C(t) \quad j = 1, 2, \dots, m \quad (94)$$

where $f_j^L(t)$, $j = 1, 2, \dots, m$ represents the j th component of a fully nonstationary vector process reflecting the “local” geological and seismological conditions of a given site and $f_j^C(t)$, $j = 1, 2, \dots, m$ represents the j th

component of a quasi-stationary corrective term, whose power-spectral density matrix has to be determined.

The terms of the evolutionary spectrum-compatible power-spectral density matrix are then given by the following equation:

$$S_{jj}^{SC}(\omega, t) = S_{jj}^L(\omega, t) + S_{jj}^C(\omega, t) \quad j = 1, 2, \dots, m \quad (95)$$

and the off-diagonal terms

$$S_{jk}^{SC}(\omega, t) = \sqrt{S_{jj}^{SC}(\omega, t)S_{kk}^{SC}(\omega, t)}\gamma_{jk}(\omega) \quad j, k = 1, 2, \dots, m; j \neq k \quad (96)$$

The corrective term $f_j^C(t)$, $j = 1, 2, \dots, m$ in Eq. 93 is assumed quasi-stationary with evolutionary power-spectral density defined by

$$S_{jj}^C(\omega, t) = a_j^2(t)S_j^C(\omega) \quad j = 1, 2, \dots, m \quad (97)$$

where $a_j(t)$ is the j th modulating function preserving the amplitude time variability of the process $f_j^L(t)$ and $S_j^C(\omega)$ is the stationary power-spectral density of the corrective process. The latter is then determined modifying the recursive formula proposed by Cacciola et al. (2004) for the unilateral power-spectral density function $G_j^C(\omega)$ related to the bilateral by $G_j^C(\omega) = 2S_j^C(\omega)$, as follows:

$$G_j^C(\omega_i) = \begin{cases} 0, & \omega > \omega_x \\ \frac{4\zeta_0}{\omega_i\pi - 4\zeta_0\omega_{i-1}} \left(\frac{RSA^{(j)}(\omega_i, \zeta_0)^2 - RSA^{(f_j^L)}(\omega_i, \zeta_0)^2}{\eta_U(\omega_i, \zeta_0)^2} - \Delta\omega \sum_{j=1}^{m-1} G_j^C(\omega_k) \right) & \omega > \omega_x \end{cases} \quad (98)$$

where $RSA^{(j)}(\omega_i, \zeta_0)$ is the target response spectrum and $RSA^{(f_j^L)}(\omega_i, \zeta_0)^2$ is the pseudo-acceleration response spectrum relatively to the “local” stochastic process and the peak factor η_U has been defined in Eq. 46

The spectrum compatibility is achieved by correcting the $G_j^C(\omega)$ of Eq. 52 iteratively once simulated response spectra are obtained through the generation technique described in Eqs. 76, 77, 78, 79, and 80 and 83, 84, 85, 86, 87, 88, and 89.

Summary

In this entry the simulation of response-spectrum-compatible ground motion processes has been addressed. Gaussian stationary, quasi-stationary, and fully nonstationary processes have been described. The assumption of stationarity of the ground motion process provided a robust relationship between the target response spectrum and the power-spectral density function of the input. This relationship determined in the early 1970s is still used by researchers and practitioners as a vehicle to develop more advanced ground motion models. Although the assumption of stationary ground motion process is physically unacceptable, the stationary model and the related power-spectral density function provide a useful tool for determining the stochastic response of structures, through handy analytical formulas. Note that the current modal combination rule (i.e., CQC) implemented in the commercial software for the seismic analysis of structures is determined using the hypothesis of stationary Gaussian ground motion process. Moreover, stationary models can be used as a vehicle for predesign structures and/or control devices in a probabilistic sense. The quasi-stationary ground motion processes have been then introduced in literature by modulating the energy of the ground motion through empirically based analytical functions. The quasi-stationary model has the advantage to be suitable for the simulation of artificial earthquakes preserving the handy analytical formulation of the stationary process. When the nonstationarity is involved, it has to be emphasized that a certain level of subjectivity is introduced to the modeling even for the simplest quasi-stationary case. Therefore, inputs from seismological and geological data are necessary to elaborate a reliable nonstationary model. Moreover, as the nonstationary frequency content of real earthquakes has been found to be relevant for the seismic assessment of structures, more advanced response-spectrum-compatible models have been proposed and discussed in

this entry. Various approaches were proposed due to the challenge involved in the relationship between the target response spectrum and the evolutionary power-spectral density function of the ground motion process. It has to be emphasized that different models are determined to match a given response spectrum (for a given damping ratio), but they might lead to completely different results for structures with damping ratios different from that used in the calibration of the response-spectrum-compatible model and also for nonlinear behaving structures. This can be considered as a pitfall in the definition of the spectrum-compatibility criteria. Finally response-spectrum-compatible ground motion models taking into account the spatial variability of the ground motion through the generally known coherence function have been also addressed. The spatial variability is of particular relevance for bridge analysis and in general for long and/or rigid structures. Numerical applications completed the description of the response-spectrum-compatible ground motion processes.

In conclusion the definition of a good ground motion model is still an open issue in the scientific community; current trends show major interest between analytical modeling and data gathered from record's databases, trying to evaluate the relevant features of the real earthquakes.

Introduction

Masonry heritage structures (MHS) constitute a countless number of different types of constructions dated from prehistory to present in which many “value contexts” (Lipe 1984) such as historic archeological, aesthetic, symbolic, social, cultural, scientific/technological, and economic are included making them a real treasury of human civilization. According to Burman (Burman 2001), their survival is essential to the spiritual, emotional, and economic well-being of humans.

The preservation of these structures concerns both life expectancy and protection from collapse occurred from earthquakes in seismic regions or from other natural or anthropogenic disasters. The former is closely related to the conservation/consolidation from decay phenomena due to the ageing effects of the environment impact on the buildings. The collapse is mostly attributed to the inherent inadequacy of historical masonry structural systems to bear horizontal loads.

The great diversity in the typology of MHS due to the various components, techniques of construction, morphology, type of reinforcement, and functionality makes the study of it, in terms of time and cost, difficult.

Moreover, internationally accepted Charters and Documents (Venice Chapter 1964) (Nara

Document on Authenticity 1994) recommend low invasive interventions for achieving a balance between keeping authentic characteristics and taking strengthening measures.

The peculiarity of the problems with MHS as well as some unforeseen failures after retrofitting in the past years led to the adoption of a step-by-step approach to strengthening, called observational method (Lowrenco 2006). By this way, a better compromise between traditional and innovative materials and techniques is achieved.

The society awareness about heritage structure preservation has globally increased internationally because of the higher recognition of the “values” associated with civilization of human genius and economy related to cultural tourism. The value of a monumental structure or area is increased after its preservation. Therefore, strategic policies of preserving built heritage have been promoted including: development of preventing seismic strengthening measures and establishing regulating frames and management systems. Technological advances in this field have fueled the market with many innovative materials and techniques or even new concepts of confronting seismic risk.

The Ancient Masonry Structures

The ancient masonry structures are composed of load bearing horizontal and vertical masonry elements which often are inadequately connected to resist seismic actions. Besides, the flooring systems and roofing forms (arches, vaults, domes) do not always provide enough diaphragm stiffening. These features, as well as the type of masonry morphology (one, two, or three leaf rubble masonry), predetermine their respond to loading (monotonic or cyclic) and the type of failure.

The choice of an appropriate and reliable analytical model for the study and assessment of a masonry structure seismic capacity prerequisites a thorough knowledge of its characteristics and behavior, as well as its pathology and degree of degradation.

This knowledge acquisition is achieved by surveying the MHS and applying on site

nondestructive measurements and other diagnostic tools of analysis at laboratory.

Masonry is a composite building material consisting of three discrete phases: units, joint mortar, and unit-mortar interface. The last is the weakest phase governing the behavior of masonry to horizontal loads.

As units may serve stone pieces shaped or irregularly cut, as well as mud bricks/earth blocks and fired bricks, or a combination of them. Successive courses of bricks are often found in stone masonry of city walls. It is also common, in large size piers or tower walls, a rubble material, or even mortar to have been used as infill.

The joint mortars are mainly lime-based mixtures of a binding system and aggregates with the following characteristics (Papayianni 2004):

- Apparent specific density 1.4–1.7
- High porosity 20–40 %
- Low strength (1–5 MPa)
- Low elastic modulus of elasticity (2–6 GPa)
- High deformability

They contain aggregates of small grains max size 4 or 8 mm not excluding greater sizes even pebbles of 16–30 mm, particularly in the cases of castle walls and churches with thick mortar joints of byzantine architecture. In earth block masonries of vernacular architecture, mud mortars are often used for jointing.

The strength capacity of the masonry depends on the strength of its components and their volume proportion in the masonry mass according to Eurocode 6, 1995. In some relevant equations found in literature (Tassios 1986), mortars' joint thickness is also taken into account for the estimation of masonry strength. Furthermore, the mortar strength is primarily influenced by the type of binding system.

Apart from the effect of masonry components on its strength, the type and morphology of the masonry (one or multiple leaf system) plays an important role to failure mechanism. For example, in three leaf masonry walls, separation of leaves is often observed (Binda et al. 2007). Moreover, if the unit-mortar interface has been weakened, shear or tensile type failure occurs easily.

In Table 1 some characteristics of often found components in ancient masonry are given for comparison with the modern materials used in construction (Papayianni and Tsolaki 1995). The structure of an ancient mortar and brick is shown in Fig. 1.

For the understanding of the behavior of an ancient masonry, the inside stress and stress-strain characteristics are measured on site by nondestructive test methods (NDT). Among the most widely used NDT are those of single and double flat jacks, sonic measurements, boroscopy, and active thermography.

Moreover, long-term monitoring of deformations by establishing a proper system of gauges is essential for the estimation of the existing stresses. In addition, the determination of mechanical, chemical, and physical characteristics of the materials by applying test methods at laboratory allows the evaluation of residual strength and elasticity of masonry, as well as the diagnosis of the decay and the degree of degradation. This holistic process of studying heritage structures is necessary because apart from cracks, a “softening” of the masonry mass may occur due to ageing or chemical attack (sulfate attack, efflorescence) that leads to significant strength decrease of both components of the masonry. For example, the strength of mud bricks is strongly influenced by their moisture content. Relevant to the effect of degradation to the strength of mortars and brick is shown in Table 2 (Papayianni and Tsolaki 1995).

Then, an analytical model for the masonry structure is adopted to study the respond of it to different scenarios of loading. The kind of applied loads, the values for strength and elasticity of masonry components, the degree of stiffness, and the safety factors have to be decided for a realistic estimation of the degree of retrofitting and selection of remedial measures. This is a job of great responsibility since there are not adequate regulative frames and every monumental structure is a particular case study (Penelis 1996).

Compatibility Issues

From experimental and analytical research works (Thomasen 2003), it is clear that the seismic

Retrofitting and Strengthening Masonries of Heritage Structures: Materials Used, Table 1 Characteristics of components of ancient masonries

Monument	Historical period	Type of mortar	Binder	Lime content %	Ap. specific density	Strength in compression (MPa)	Brick plates (cm)	Absorption (%)	Strength in compression (MPa)
Galerius palace	Roman	Structural	Lime + pozzolan + soil	30	1.7	3.0–4.0	30 × 40 × 6	15.4	8.0–10.0

Retrofitting and Strengthening Masonries of Heritage Structures: Materials Used, Table 2 Influence of the grade of deterioration on the bricks and mortars

Monument	Material	Absorption %	Salt content	Cracking	Strength in compression MPa
St. Panteleimon	Brick 1	14	Low	No	17.1
Fourteenth century AD	Brick 2	28	High	Yes	5.1
Hagia Aikaterini	Mortar 1	18	Medium	A few	2.5
Thirteenth century AD	Mortar 2	20	Medium	A few	1.9
Acheiropoietos	Mortar 1	20	Medium	No	3.3
Seventh century AD	Mortar 2	35	Medium	Yes	1.5

capacity of masonry is inherently low and anti-seismic protection demands explicitly strengthening. Moreover, MHS materials suffer very often from decay, and consolidation of the masonry mass must precede before any strengthening.

The dilemma is how much strengthening is appropriate for the historic structures, which do not conform to modern seismic design codes, addressing concrete constructions. Internationally accepted documents (Venice Charter 1964, ICOMOS, (Burras Charter 1981, 1988), Nara Document on Authenticity 1994), require respect to the “values” of monumental character structures, including architectural integrity, authenticity of the materials, and their morphology. What is recommended in retrofitting is to use compatible to authentic materials and traditional skills for their appliance.

There are many poor examples of interventions on monuments with concrete, which was supposed to cooperate as repair material with the old masonry. The destructive consequences from the use of incompatible to authentic matrix repair materials are mostly related to different physico-chemical characteristics of cement-based or polymeric matrix repair materials, which block the moisture movement, because of very low porosity and different porosity properties in comparison to old mortars. In addition, the aforementioned repair materials differ in elasticity from the existing old ones and consequently in deformability under the action of mechanical or hydrothermal loads.

However, for MHS in seismic regions, which are to be inhabited the value “safety” is of first priority. Therefore, strengthening methods are selected to be technical and cost-effective, as well as less invasive (Tassios and Mamillan 1985).

Homogenization and consolidation of the old masonry mass by inserting new repair materials is often applied with or without any reinforcement technique. It is worth mentioning how compatibility aspects could be interpreted in technical terms concerning their design (Papayianni 2004) (Van Balen et al. 2005). The most important characteristics or criteria by which compatibility is driven are:

- Surface features (color, texture, roughness)
- Composition (type of binder, granulometry of aggregate)
- Strength level (compressive, tensile)
- Elasticity (modulus of elasticity, deformability)
- Porosity (porosity, pore size distribution, capillarity)
- Coefficient of thermal dilation

These criteria have been applied in designing the repair mortars of a great number of interventions in Greece (Papayianni 2004), from 1990s to present, and proved very successful and long lasting. It must be pointed out that compatible repair material does not mean imitation of the authentic one. What is pursued is that having understood the functionality of the masonry, the repair material should not unsettle the long-term balance between local environment and structure and change its behavior. Based on experience from practice, it seems that by adopting mixed-type binding systems and suitable admixtures, the properties of repair materials may be adjusted to meet compatibility criteria.

Materials and Techniques for Retrofitting and Strengthening Masonry Heritage Structures

Introduction

The increasing awareness of the society about safeguarding heritage buildings promotes strategies of preventing their seismic retrofit. Cracks and other damages must firstly be repaired for reintegrating the continuity of the masonry corpus and then proceed to strengthening

alternatives. By this way, the resistance to earthquake and durability of MHS are globally improved. Of course, a thorough comprehension of the behavior of MHS must precede.

A solution of another concept to the problem is to reduce the seismic impact in the heritage structure by using a base isolation system (BIS) with supplementary viscous dampers at the base and the top of the building (Saito 2006). A successful example is the case of Los Angeles City Hall in which the BIS allows to remain stationary while the ground moves up to 500 mm in horizontal direction (Nabih 1996).

The methods of interventions are practically referred to materials and techniques. They are divided into irreversible methods, in which new materials are embodied in the masonry corpus and cannot be removed, and reversible ones, in which new materials are able to be activated on the surface or near the surface of the masonry undertaking local loads and can be replaced.

Irreversible Interventions

Irreversible interventions aim at consolidating the mass of the masonry, in particular when it suffers from softening due to intensive deterioration. The most common are:

- Grout injection
- Flowable mortar infills
- Deep repointing
- Reconstruction of masonry missing parts
- Punching steel bars (stainless steel) to saw cracks.

Of course, these interventions contribute to strengthening, but often additional techniques are applied to increase diaphragm stiffening and achieve adequate connection of horizontal and vertical structural elements of old masonry, aiming at increasing its seismic capacity. In the past, jacketing of piers with concrete, adding concrete beams as “chainage” or masonry confinement, has been widely used. They were characterized as invasive interventions altering the function and character of the old structure. Similarly, ferrocement surface coating or casting shotcrete over a steel mesh has been used for strengthening.

In irreversible interventions a major compromise between principles of restoration and safety and durability issues for the constructions is continuously under question. As declared in Nara Document (1994) “keeping the authenticity of heritage structures, materials and architecture is of great importance since all the values of a monumental or listed construction are transferred to future generation with materials.” However, as mentioned in the previous entry, in the case of inhabited historical buildings in urban areas which are to be preserved but also to be safe, authenticity issues are not of first priority.

Grouts and mortars are inserted into the masonry mass using different techniques to fill cracks, void in brick-mortar interfaces, and reduce the intrinsic heterogeneity and anisotropy of the masonry. After longtime and extensive research works and experience from field applications, some recommendations about designing grouts and mortars are found in literature (Tomazevic 1992). The conflicting aspects encountered in designing grout and mortar for repair of MHS make it an attractive research topic of paramount importance for the preservation of the heritage structures and their durability.

In most cases a tailored to the specific monumental structure grout/mortar mixture is proposed, taking into account the characteristics and pathology of the structure. Ready mixed grouts or mortars are not usually used since they do not often comply with specific requirements imposed by compatibility. Responsible for the design and application technique is the engineer who will select the binding system. This may be a combination of lime and pozzolan, with small quantities of cement, reactive silica, and admixtures, for rheology improvement, strength development, and volume stability. Commercial hydraulic lime is often used as an alternative binder. A series of tests are recommended for ensuring their quality (Toumbakari 2002).

Grouts

The technique of the consolidation with injection of grouts was at first well known in geotechnical and concrete engineering. Later, it was

extended for the homogenization of the mass of heritage structure. From the 1970s onward, grout injections have been used in many historical buildings and monumental structures. Grouted anchors are often used when tierods are inserted into masonry to improve tensile strength capacity. In 1990–2000, a number of research works and PhD thesis (Miltiadou 1990) (Valluzzi 2000) (Toumbakari 2002) have contributed much to the evolution of materials and techniques improving the quality and performance of the grouts.

The grouts are slurries of hydraulic nature binding system with or without inert fines and admixtures. The water/binder ratio is usually around 1.0. To be efficient, grouts must present in fresh state adequate fluidity and consistence, penetrability, and volume stability. In addition, after hardening they must develop good bonding within old masonry microstructure and mechanical strength.

To keep compatibility principles in designing grouts for MHS implies the selection of inorganic and relatively low strength potential binders, such as lime-based binding systems, which are the constituents of the most joint mortars of ancient masonries. An exception is the earth block masonries, in which the soil is the main binder for blocks and mortars and grouts should be soil-based mixtures.

In the first grouting intervention on MHS, portland cement was used as binder, but gradually the cement was diluted with lime or replaced by hydraulic lime or ternary binding system of the lime-pozzolan-cement plus some additives. Based on experimental work some researchers suggested (Toumbakari 2002) that the grouts injection results in significant strengthening if its binding system contains at least 30 % of mass portland cement.

An example of application with mixed-type binding system constitutes the consolidation of masonry element of the Byzantine Church Acheiropoietos (dated from the seventh century AD) by grouting in the 1990s with the following mixture. The choice of the binding system was based on the experimental study of materials and trial mixtures.

Retrofitting and Strengthening Masonries of Heritage Structures: Materials Used, Table 3 Characteristics of lime-based grouts

Parts by weight					W/B	Fresh state properties			Compressive strength (MPa)	
Hydrated lime	Hydraulic lime	Natural pozzolan	White cement	Brick dust		Fluidity (sec)	Penetrability (sec)	Vol. stability (%)	28d	90d
1					1.06	10.8	3.15	1.5	–	0.69
	1				0.61	9.33	3.41	0.7	1.76	–
1		1			1.10	9.8	4.8	1.2	0.89	4.45
1		0.8	0.2		1.00	9.34	3.1	0.8	1.73	4.79
1		0.7	0.3		0.97	9.70	2.10	0.6	2.51	5.39
1		0.6		0.4	0.93	9.59	2.10	1.5	0.82	3.33
1		0.6	0.2	0.4	0.90	10.20	1.95	1.0	1.72	4.75

Composition of grout used in Acheiropoietos:

Hydrated lime: 40 %

White cement: 30 %

Ground pozzolan: 15 %

Brick dust: 15 %

Epoxy resin grouts which are widely used in filling cracks in concrete members are inappropriate in MHS grouting since the different nature of synthetic materials in terms of water and vapor impermeability makes moisture to be entrapped inside the MHS that is detrimental for old masonry. The ideal grout composition for MHS should present chemical and physical compatibility with the matrix of the MHS mortars like the transfused blood to human body.

The use of additives and admixtures in small quantities results in modifying grouts to develop the desirable properties. It should be pointed out that lime-based mixtures keep their fluidity for longer time than those of cement-based ones. This is a significant benefit for working in the field, especially in the summer period of Mediterranean climate.

Some lime-based grout mixtures with their characteristics in fresh and hardened state are shown in Table 3 (Papayianni and Pacht 2012).

In literature, there are recommendations (Papayianni 2004) about the selection of raw materials and methods of testing grout

performance and checking the filling effect after hardening. Some of them are mentioned below:

- The hydrated lime powder must be reactive and its reactivity could be checked by measuring $\text{Ca}(\text{OH})_2$ content by DTA-TG. Apart from lime hydroxide, hydraulic lime is also used in grouts because it hardens itself in humid environment and it is more convenient in the field work. However, there are differences between alternatives, concerning strength development and microstructure.
- Natural pozzolans are considerably activated if milled and contribute to earlier strength development, as well as to long-term strength.
- Sand or gravel of selected max size must present an even granulometry and be free of organic and soluble salts. Limestone dust or brick powder is also often added as fines.
- The salt content of all constituents of the grout mixture should be as low as possible. For example, efflorescence of sulfates is often observed due to sulfate content of brick powder. Even superplasticizers used to arrange fluidity must be free of sulfates.
- In case of cement addition it should be of low alkali and sulfate content.

Fluidity is commonly checked by Marsh cone (ASTM C939-87), while penetrability or injectability is tested by using the sand-column test (NORM NFP 18–891, 1986, EN 1771).

For volume stability the test method according to DIN 4227 Teil 5 standards is used. Furthermore, other more specific tests may be used, such as water retentivity and drying shrinkage, according to ASTM C1506 and ASTM C474, respectively.

Cracks, voids, and other discontinuities inside the mass are detected by nondestructive methods, such those of ultrasonic sonometer, radar, and IR thermography before and after the grout hardening (Tomazevic 1992). A draft assessment of achieved filling is made by this way.

Flowable Mortars

In case of cracks of high opening (2–10 cm), it is preferable to use a flowable mortar instead of grout, because the sand content of greater grain max size (0–8 mm) contributes to volume stability reducing shrinkage cracking. If necessary, stainless steel rods are often inserted transversally to the crack in order to saw the separate parts of masonry. The binders of flowable mixtures may consist of hydrated lime powder, pozzolan, and fines, such as limestone powder added by superplasticizers and viscosity modifiers. The composition of the flowable mortar must be based on the analysis of the existing old mortar. It has also to be tested for adequate flowability, even one hour after making the mixture, following the known test methods for fluidity and robustness, in relevant European guidelines 2005, such as flow table and L-box.

A type of flowable mortar has been applied in filling cracks of a part of wall masonry in Galerius ensemble, by gravity or low pressure. The composition and mechanical characteristics are given in Table 4 and Fig. 2.

Deep Repointing Mortar

Retrofitting of masonry joints with mortar is a common intervention work of restoration projects. Before designing the mortar’s composition, a systematic analysis of existing mortars is made to meet requirements for compatibility and a decision is made about strength demand and durability. The selected traditional type binding system, such as lime-pozzolan, may also include a small percentage of brick bust or cement and admixtures to meet the compatibility and

Retrofitting and Strengthening Masonries of Heritage Structures: Materials Used, Table 4 Composition and strength of a flowable mortar applied in parts of Galerius ensemble

Raw materials	Parts by mass
Hydrated lime powder	1
Ground pozzolan	1
Limestone filler	0.7
Sand (0–4 mm)	6.5
Water/binder ratio	0.61
Superplasticizer (% by mass of binder)	2.4
Retarder (% by mass of binder)	0.3
Porosity	20.8 %
Flexural strength (specimens: 4 × 4 × 16 cm)	2.65 MPa
Compressive strength (specimens: 4 × 4 × 16 cm)	6.5 MPa

durability requirement. Apart from binders, coarse aggregates are often used especially in thick mortar joints. Some examples of these mortars used in interventions are shown in Table 5.

Reversible Interventions

In general, they are considered low invasive and effective in terms of expectancy and resistance to environmental conditions. In most of this type of interventions, the materials are industrially manufactured, standardized, and commercially known with brand names. They are usually applied with specific technique. The problems presented in practice are rather related to technique than to materials.

An analytical assessment of how the MHS responds to earthquake is necessary, since the positions and the degree of retrofitting must be known before any type of reversible intervention.

A long list of this type of interventions could be mentioned since there are many technological advances in this field. Some of them are:

- Pre-stressed (stainless) steel cables offered many solutions in the last decades of previous century (Fig. 3; Ignatakis and Stylianidis 1989).
- Stainless steel bars or strips into bed joints repointing with lime-based repair mortars.

Retrofitting and Strengthening Masonries of Heritage Structures: Materials Used,

Fig. 2 Galerius palace ensemble, third century AD. Cracks filled with flowable lime-based mortar

Retrofitting and Strengthening Masonries of Heritage Structures: Materials Used, Table 5 Proposal of deep repointing of Byzantine monuments

Monument: Saint Nicholaos Church, Aiges, Sparti (Post Byzantine period)

Analysis of mortar samples

Color: grayish white

Stratigraphy: One layer

Stereoscopic Observation: Compact paste with micropores, cracks with re-crystallized secondary material (photo) with concentration of calcite (photo). High content in aggregates, max size up to 8–10 mm, of mixed-type siliceous and calcitic origin

Compressive strength: 14.1 kg/cm²

Porosity: 19.15 %

Specific gravity: 1.74 g/cm³

Chemical composition %:

Na ₂ O	K ₂ O	CaO	MgO	Fe ₂ O ₃	Al ₂ O ₃	SiO ₂	L.I.
0.36	0.33	31.5	6.18	1.04	3.29	27.7	30.0
Content in anions:			Cl ⁻	NO ₃ ⁻	SO ₄ ²⁻		
			0.17	0.12	0.19		

Insoluble residue: 48.8 % by mass

Gradation curve: Max size of grains: 8 mm

Proposal of repair mortar

Constituents	Parts by weight		
Hydrated lime	1		
Pozzolan ground (milaiki gaia) (10 % residue on 45 µm sieve)	1		
River sand (0–1 mm)	0.2		
Local limestone crushed (2–4 mm)	1.6		
Coarse limestone (4–16 mm)	0.2		
Superplasticizer (free of sulfates) 1 % by mass of the binder			
Water required for 15 ± 1 cm expansion on the flow table			
The trial mixes showed that the achieved 28-days compressive strength ranges from 19 to 25 kg/cm ² and the porosity from 17 % to 20 %.

R

Bars or strips could also be made of carbon fiber reinforced polymer (CFRP) covered with lime-based mortars (Modena and Valluzzi 2003).

- Metallic braces anchored on the masonry for confinement of the out of plane failure deformations (Fig. 4; Ignatakis and Stylianidis 1989).
- Bonded to surface fiber reinforcement with polymer or cementitious matrices (FRP or FRG).

There is much progress in the materials and techniques of anchoring for FRP/FRG textiles, resulting in higher performance and cost-

effectiveness, but still these types of interventions require special and expensive work. There are different types of advanced fiber reinforced sheets or grids of polymeric (FRP) or cement-based (FRG) matrix bonded on the surface of masonry elements. The use of this type of retrofit has impressively increased and continuously evolved. For example, tie bars are placed on the under strengthening areas of masonry with Shape Memory Alloy (SMA) devices by which recover from strain and relief of stress are achieved (Desroches and Smith 2004).

Retrofitting and Strengthening Masonries of Heritage Structures: Materials Used, Table 6 Characteristics of fibers of FRP(s)

Type of fibers	Glass	Carbon	Aramid	Steel
Tensile strength (MPa)	1,300–3,400	2,000–5,600	2,500–3,620	1,500–3,500
Modulus of elasticity (GPa)	22–62	150–325	48–76	185–210
Ultimate strain (mm/mm)	0.03–0.05	0.01–0.015	0.02–0.036	0.04
Coefficient of thermal dilation (10^{-6} m/m/°K)	5.5	0.0	–0.5	6.5
Density (g/cm ³)	2.5–2.6	1.7	1.4	7.9
Melting point (°C)	1,100	310	420	1,300

Bonded to Surface- Reinforcement Techniques

These low invasive alternatives have started to be used in construction from the 1990s. They consist of a fibric system and a matrix system bonded in different forms, such as pultruded bars, sheet, or textiles and grids. The most known fibers are steel, carbon, aramid, glass and alkali-resisting glass (AR glass), basalt and biocomposites (flax, hemp), or recycled biopolymers based on lignin, cellulose, and pectin. Some characteristics of fibers are found in the literature in Table 6 (Meier 1995). Carbon fiber reinforced polymer sheets (CFRP) and steel fiber reinforced polymer sheets (SFRP) are the most widely used products in reinforcing constructions (Fig. 5). They

undertake tensile stresses developed in parallel to fiber direction. The matrix in which fibers are embodied unidirectionally or bidirectionally is polymer, such as epoxy resins, polyester, and vinyl ester. In cement-based textiles or grids, a polymer-modified cement mortar with 1 % by volume long chopped AR glass fiber is used. Fibers could be categorized in three classes (Casadei and Agneloni 2009; Mitolidis 2009):

- Of high modulus of elasticity, such as different qualities of steel and carbon
- Of medium modulus of elasticity such as aramid, basalt, and glass
- Of low modulus of elasticity such as Flax and Hemp

Indicative values for the characteristics of the epoxy resin matrices are:

- Density 1.1–1.7
- Modulus of elasticity 0.5–20GPa
- Flexural strength 9–30 MPa
- Ultimate strain 0.5–5 %

The main type of failure of surface bonded CFRP(s) concerns the development of considerable shear stresses on the surface leading to detachment. That is why the anchorage length must be estimated for each type of matrices and be based on reliable measurements of bonding.

The procedure of applying FRP includes:

- Check the bonding capacity of masonry substrate.
- Leveling the surface to succeed good bonding that is essential for transferring stresses in particular in the case of not strong anchorage.
- Apply FRP sheets on dry surface with good quality of adhesive material.
- Ensure sufficient anchorage. Metallic haunch connections are preferable for low invasive FRP.
- Use of proper dye for protection from UV radiation.

More details are available in literature (ACI 440 2R-08, 2008).

When retrofitting masonry walls or strengthening arches and domes, the values of practical interest in relation to FRP are:

- Ultimate tensile strength (i.e., 5–6 MPa)
- Ultimate elongation (i.e., 1.62 %)
- Transition zone tensile stress (i.e., 2.1 MPa)
- Tensile modulus of elasticity (i.e., 0.37GPa)

As advantages of FRP are considered the following:

- The low weight or high strength to weight ratio
- The relatively easy installation and high productivity of the work
- The minimal dimensional change of the masonry elements

- The resistance to corrosion, chemical attack, and environmental impact

However, many disadvantages have also been noted mainly because of the polymer nature of the matrix, such as:

- Low resistance to fire
- Degradation of polymeric matrix by UV
- Application needs special equipment and specialized staff as well as dry surfaces and low temperatures
- The incompatibility of resins to masonry structure has an impact to the bond of FRP on masonry surface. Moreover, FRP may create secondary side effects that make the benefits of reversibility questionable. This occurs because of the lack of vapor permeability that leads to moisture accumulation inside the masonry mass which favors deterioration phenomena, particularly in the case of large masonry area rapping with FRP. Furthermore, FRP or AR fiber glass textiles exhibit brittle failure mechanism when their bonding is based on adhesion and friction. In fiber grids with cement-based matrix, these effects are mitigated.

Some outstanding examples of MHS strengthening with FRP mentioned in literature, such as the strengthening of the San Vitale Church in Parma, Italy, and the repair of the monastery of St Andreas, Mount Athos, 2011 (Figs. 6 and 7).

An interesting evolution in the field of reversible external intervention is SMA devices, which are systems of advanced technology applied in MHS for defending earthquake. The main materials of SMA are alloys of NiTi, which recover from large strain through heat action. They are considered superelastic and high damping systems so as by the removal of stress a recovery from strain occurs. The high cost, the difficulty in handling the material because of its hardness, and the welding deficiency are mentioned as disadvantages, as well as the dependency of the SMA properties from the temperature and their sensitivity to compositional changes of alloys. (MANSIDE Consortium 1998).

An example of SMA application, mentioned in literature, is the first application of these

devices in S. Giorgio Church in Trigano, Italy, by Prof. Indirli (2001) (Indirli et al. 2001) and reinforcing of St. Francisco of Assisi Church by Professors Groci and Gastellano (Groci 2001).

Summary

Masonry Heritage Structures (MHS) have inherent weakness in carrying horizontal loads, and their preservation and protection in seismic areas require retrofitting and strengthening interventions. However, principles of philosophy of conservation about compatibility and keeping authenticity should be followed in parallel to safety and durability issues valid in any type of construction inhabited, according to

modern codes and regulations for anti-seismic design of structures.

The nature of building materials of old masonries which are porous and of low strength capacity is different from modern compact cement-based building materials (reinforced with steel bars) and of low porosity, high bearing capacity in compression, and bending and tensile loads. Similarly, materials of organic polymer-based matrix are impermeable and hardly cooperating with inorganic matrix materials. These contradictions introduce particular difficulties in retrofitting and strengthening heritage masonries enhanced by the fact of the great variety of masonry types, in terms of their components, way of constructing, functionalism in the structural ensemble, and various loading conditions.

After earthquakes of the last three decades of the twentieth century in Italy and Greece, countries with a tremendous heritage building asset, the MHS “de facto” separation in historical masonry buildings of urban areas and monumental buildings was followed for emergency repairs. This temporary separation allowed more freedom in compromising safety and compatibility issues in the case of historical buildings of old urban centers, while compatibility and authenticity issues prevailed in the case of monumental buildings. This option was also suggested by distinguished scientists (Tassios and Mamillan 1985), because it helps decision makers about the degree of strengthening.

Addressing properly the aforementioned issues in lifesaving interventions on MHS pre-requisites the consideration of a holistic approach of analysis of existing structures. This involves using measurements on site and at laboratory, as well as assessment of MHS behavior by adequate models. In this manner, a thorough understanding of the structure can be obtained before deciding about repair materials and techniques.

In the past, many failures occurred concerning mainly side effects due to invasive retrofitting interventions on the MHS ensembles. The current evolution in this field focuses on the development of compatible grouts, flowable mortars, and repointing mortars for irreversible type consolidation of the mass of the masonry corpus. Besides, steel and other fiber reinforcement bonded on the surface of masonry with materials of polymeric- or cement-based matrix are used as reversible interventions.

Advances in the field of irreversible interventions could be considered the use of upgraded lime-based grouts and mortars, i.e., with addition of new generation admixtures prolonging fluidity and increasing volume stability, or by using nano-modified slurries for the enhancement of bonding of interfaces between old and new materials.

Furthermore, new types of reinforcement are expected, which would be light and resistant to environmental influences, providing a high deformability capacity with strong and yet less harmful anchorage, and meet aesthetic and compatibility requirements are some expectations in reversible strengthening of HMS.

Moreover, the quality of materials and intervention works is of primary importance for the longevity and economy of interventions. However, the system of regulations, recommendations, proper test methods, and specific standards has not been fully developed, in spite of continuous efforts of the last decade on national and European level. There is still a gap between knowledge and practice, but undoubtedly the continuous education and joint research efforts, as well as the awareness of the society about safeguarding cultural patrimony, have resulted in significant improvement of consolidation and strengthening works.

Introduction

Buildings or civil engineering works in seismic regions constitute very large-scale property investments which affect the lives of a great number of people.

The original construction and any later retrofitting and strengthening for seismic protection require **the coordination** of many people, including investors, engineers, foremen, technicians, and laborers, in a large, organized effort. The number of people participating in the construction of the works or of the interventions and the number of subsequent users are sources of risk for people and goods due to failures during construction or during the life-time of the works. For the above reasons, very early in human history, organized societies incorporated into their **penal** and **civil** codes articles against the violation of rules of construction, providing for **penalties** and **liabilities** and aiming in this way to reduce the incidence and effects of failures on goods and people. It is interesting to note the reference to this issue in the Code of Hammurabi (1772 BCE) (King 1915) (Fig. 1).

At the same time, rules for building procedures have been established, accompanied by quality control systems. All these measures constituting what we call today **quality assurance** have on one hand aimed at reducing probabilities of failure and on the other at creating a framework of checkpoints for the objective determination and dissemination of liabilities to the personnel involved in the construction of buildings and public works.

For a clear approach to issues of quality assurance and liability in regard to retrofitting and strengthening of buildings or civil engineering works, it is necessary to clarify first the various actions of **assessment**, **design**, and **construction** in retrofitting where mistakes may occur and therefore where liabilities and penalties may arise.

Taking all the above into account, the following structure will be adopted in the following sections:

- Steps of procedure for seismic retrofitting and strengthening of buildings and civil works
- Quality assurance mechanisms applied at each step of the retrofitting procedure
- Liabilities emerging in case of defects or failures

Retrofitting and Strengthening Procedures

Seismic Assessment

General

The seismic assessment of existing buildings has as its main objective making decisions about the need for retrofitting each individual building. In this respect seismic assessment always precedes retrofitting activities. Keeping in mind that the retrofitting cost (structural–nonstructural) is very high, ranging around a mean value of 10–12 % of the original cost of construction, and that the number of buildings or civil engineering works involved in a mitigation program is usually very large, it is apparent that an evaluation procedure must be established **for screening** the buildings or works under consideration in successive steps of accuracy, until the number of buildings or other works (e.g., bridges) chosen for eventual intervention has been radically reduced.

National programs for seismic risk mitigation through retrofitting must be classified as either **post-earthquake** or **pre-earthquake**. The first category is triggered by a strong earthquake and the damage caused, while the second category is triggered by “**political decisions**” for seismic risk reduction for a special category of works such as schools, hotels, hospitals, etc. It is apparent that the first category is the most usual, as it is obligatory for a government to activate such a program after a disastrous earthquake. No matter which one of these two categories is followed, the flowchart of the whole procedure through rehabilitation is given in Fig. 2 (Penelis and Penelis 2014).

229. If a builder build a house for some one, and does not construct it properly, and the house which he built fall in and kill its owner, then that builder shall be put to death.

230. If it kill the son of the owner the son of that builder shall be put to death.

231. If it kill a slave of the owner, then he shall pay slave for slave to the owner of the house.

232. If it ruin goods, he shall make compensation for all that has been ruined, and inasmuch as he did not construct properly this house which he built and it fell, he shall re-erect the house from his own means.

233. If a builder build a house for some one, even though he has not yet completed it; if then the walls seem toppling, the builder must make the walls solid from his own means.

Retrofitting and Strengthening Measures: Liability and Quality Assurance, Fig. 1 The Code of Hammurabi: reference to building defects liabilities and penalties (King 1915)

Retrofitting and Strengthening Measures: Liability and Quality Assurance, Fig. 2 Flowchart for pre- and post-earthquake assessment and retrofitting (Adapted from Penelis and Penelis (2014), C.R.C. Press)

Post-earthquake Assessment

General Post-earthquake assessment activities must be classified into two main levels:

- Emergency post-earthquake damage inspection
- Post-earthquake seismic evaluation

The first category of inspections is performed by the State. During this procedure, damage characterization for each independent building and designation of its damage level are carried out. At the same time, emergency propping activities and demolitions are executed for direct risk reduction due to aftershocks.

The second category is performed by the owners of each individual building: During this

procedure the residual resistance of every individual damaged structure is assessed and the degree of intervention is decided, that is, **repair** or **strengthening** of the structure.

Emergency Post-earthquake Damage Inspection A strong earthquake puts on trial not only citizens but the State itself. The authorities have to face chaotic situations due to lack of information, the extent of the affected region, and the multiple requests for assistance and for inspections of damaged buildings. The foregoing remarks aim at describing the environment in which the structural engineer is called upon to do an emergency post-earthquake damage inspection.

This should be the prevailing element for the organization of the earlier operation. Indeed,

since damage evaluation sometimes involves thousands of buildings that have to be assessed in a short period of time by hundreds of engineers, a special procedure has to be followed, completely different from that used for the detailed evaluation of a single building before retrofitting and even from that used in pre-earthquake assessment programs.

Therefore, after a strong earthquake, only a **damage-oriented evaluation procedure** may be implemented. In this case structural engineers come face to face with buildings or public works struck by the earthquake, without being able to use the scientific tools that they possess, namely, **in situ measurements, laboratory tests, and the analysis**. They are compelled by circumstances to restrict themselves to qualitative evaluations and make decisions based solely on **visual observation**, using at the same time their **good engineering judgment**.

In any case the engineer can make one of the following decisions after this first contact with the damaged structure:

- (a) Allow use of the building without restrictions, designating it as **“green.”**
- (b) Classify it as temporarily unusable with limited access due to local damage, designating it as **“yellow.”**
- (c) Classify it as out of use because of extensive damage, designating it as **“red.”**
- (d) Classify it as near collapse and activate proping measures together with restrictions on approaching the area around the building, or even demolitions.

The assessment procedure is depicted in the flowchart in Fig. 3 (Penelis and Kappos 1997). From the above diagram it can be seen that the whole procedure is articulated at three levels related to the seriousness of damage and is therefore aimed at reducing the risk of assessment errors.

The procedure described above, being to a great degree subjective, requires special concern for the formation of a proper quality assurance system. At the same time this subjectivity should be taken seriously into account for

liability issues. All these will be examined in detail in the sections that follow.

However, it should be noted that, as may be observed in the case of Thessaloniki (earthquake of June 20, 1978), the results of emergency inspection should be characterized as rather reliable, since the repair or strengthening that followed, which was based on a detailed post-earthquake assessment, involved (Penelis et al. 1987):

- 11.5 % of the number of “green” buildings
- 45.2 % of the number of “yellow” buildings
- 81.9 % of the number of “red” buildings

Post-earthquake Assessment The main criterion for a post-earthquake assessment and the decision on the degree of retrofitting is the extent of damage and its seriousness. This approach radically decreases the number of interventions and, therefore, the retrofitting cost of an affected region and the time required for the whole operation.

Based on the above, the approach to the intervention procedure may be stipulated as follows:

- In structures with light damage of local nature, intervention should be limited to **repair** (Fig. 4).
- In structures with extensive or heavy damage, global-type intervention should extend to **strengthening** of the structure.

It is obvious that only buildings or other types of structures posted as “yellow” or “red” are evaluated. The evaluation is a damage-oriented quantitative procedure, and it is based mainly on the ratio of the residual seismic resistance V_D of the damaged structure to its capacity V_c before damage (Fig. 4).

The result of this assessment is a decision either to repair (local damage) or strengthen (global-type damage).

Strengthening is carried out for buildings following the procedure specified by FEMA 356, 2002/ASCE SEI 41–06, or EC8-3/2005 (see next paragraph, tier 3).

Retrofitting and Strengthening Measures: Liability and Quality Assurance, Fig. 4

Schematic presentation of the difference between “repair” and “strengthening” (From Penelis and Kappos (1997), with permission of C.R.C. Press)

Pre-earthquake Assessment

Keeping in mind that the majority of the buildings in use do not comply with modern seismic codes and therefore present various levels of vulnerability, it has been realized, particularly in the USA since the early 1980s, that a drastic reduction of seismic risk could be achieved only by an “active” intervention in the existing building stock. Thus, a framework of procedures for seismic assessment of buildings has been developed in various countries, with that in the USA being the soundest (FEMA 310/1998/ASCE 31–02).

In most cases this procedure is articulated in three successive steps of higher detail and accuracy from the first step to the third.

The FEMA 310/1998/ASCE 31–02 procedure is presented in the flowchart in Fig. 5.

The above standard provides for a **three-tiered procedure** aiming at the localization of buildings that might be hazardous after a strong earthquake and for the **life safety** of buildings intended to be used for **immediate occupancy**. These **three tiers** are the following:

- Screening phase (Tier 1)
- Evaluation phase (Tier 2)
- Detailed evaluation phase (Tier 3)

Screening phase, Tier 1, allows a rapid seismic evaluation of the building. The level of analysis required at this step is minimal.

Tier 2 includes a complete but simplified linear analysis of the building or any similar structure.

Tier 3 includes a detailed seismic evaluation and must be assigned to the detailed retrofitting

procedure (FEMA 356, 2002/ASCE SEI 41–06, or EC8-3/2005).

Detailed Seismic Assessment and Retrofitting

General

As clarified in section “[Seismic Assessment](#),” detailed seismic assessment and retrofitting of buildings or similar works is activated after a seismic evaluation procedure has been completed and structures designated for detailed investigation and retrofitting have been identified.

Whether or not the designation of these buildings is the result of a pre-earthquake or a post-earthquake procedure, the method for this detailed assessment and retrofitting is the same, and for the time being, this is specified by FEMA 356, 2002/ASCE SEI 41–06 in the USA and EC8-3/2005 in the EU. It should be noted that any retrofitting activity aims at raising the seismic performance of an existing structure to a level similar to that of new structures designed and constructed in accordance with contemporary seismic codes.

Detailed Assessment

The task of detailed assessment is the quantitative determination of the existing global safety factor of the structure and at the same time the existing local safety factors in all critical sections of the structural elements.

In this context, on one hand the need for eventual retrofitting is verified, and on the other these results constitute a very good guide for the retrofitting scheme that will be adopted for the strengthening of the existing structure.

Retrofitting and Strengthening Measures: Liability and Quality Assurance, Fig. 5 Evaluation process according to FEMA-310/1998/ASCE31-02 (From FEMA-310/1998/ASCE 31-02 Handbook for the Seismic Evaluation of Buildings, Federal Emergency Management Agency, Washington D.C. with permission)

Bearing in mind that the quantification of safety issues requires the existence of reliable information on the structure, the foundation ground, and the seismic actions that will be used as an input in well-defined analytical structural procedures, it is evident that a detailed assessment procedure specifies:

- Requirements for the necessary information of the structure itself, the foundation ground, and

the seismic actions, based on site investigations, laboratory tests, investigation of existing drawings of past conditions, etc.

- Specified methods of analysis
- Specifications of the limit state that should be examined
- Global and local verifications of seismic resistance

Design of Seismic Retrofitting

The design procedure for seismic retrofitting includes the following steps:

- Conceptual design
- Analysis
- Safety verifications
- Drawings
- Technical reports

The scope of this entry does not allow detailed reference to the above steps. However, brief reference should be made to some important issues:

- Conceptual design is of particular importance, because it formulates the type and configuration of the retrofit scheme.
- Analysis and safety verifications need special consideration, as the prevailing procedure is the **displacement-based** design, in contrast to the **force-based design** which is the prevailing procedure for new seismic-resistant structures.
- Drawings should include three groups, namely:
 - Demolition drawings
 - Temporary propping drawings
 - Retrofitting drawings
- Technical reports should be similar to those for new structures.

Execution

The execution of retrofit works must be carried out by a qualified contractor.

During retrofitting activities, due to the demolition works on the structure, temporary propping works are required. This stage of the works is the riskiest, as unexpected collapses and casualties may occur.

In retrofitting activities special materials and techniques are used that are very rarely applicable to new structures. Therefore, a detailed study of their characteristics is required, as well as careful supervision during their application.

The form and the extent of interventions cannot be completely foreseen at design stage. The contractor and his technical staff are often compelled to improvise in order to adjust materials and techniques to the needs of unexpected existing conditions.

Concluding Remarks

The above brief presentation has been considered necessary for treatment of the quality assurance and liability issues for retrofitting and strengthening which follow.

In fact, although seismic assessment, retrofitting, materials, and techniques are presented by other authors in detail in other chapters of this encyclopedia, it was not possible for us to develop quality assurance and liability issues for activities that have not been incorporated, even summarily, in a properly integrated structure, in compliance with the steps that follow.

Quality Assurance

General

For the clarification of various issues that will be presented below, some definitions of quality management must be given in advance:

- **Quality** of a work (e.g., retrofitting) or of an action (e.g., assessment) is its conformity to performance requirements specified by the code.
- **Quality assurance** (ISO 8204 text, CEB, Bulletin 241 [1998](#)) expresses all the planned and systematic activities implemented within a quality system and demonstrated as needed, in order to provide adequate confidence that a work (e.g., retrofitting) or action (e.g., assessment) will fulfill performance requirements for quality.

Retrofitting and Strengthening Measures: Liability and Quality Assurance, Fig. 6 Conceptual form of quality system (Adapted from CEB Bulletin 241 (1998). Quality Management guidelines, Thomas Telford, London)

- **Quality plan** is a document setting out the specific quality practices, resources, and sequence of activities relevant to a particular work or project.
- **Quality control** in the construction industry is a set of documented procedures used to monitor principal activities and processes during realization of a project in order to reduce nonconformities with performance requirements to a minimum. It is therefore applied during all stages of the project, including design, work preparation, execution, and handing over.

Over the last 20 years, an effort has been made to reform the quality assurance system. In the past, primary importance was given to the control of the quality of the final product and of services at the interfaces during the construction process. Current quality assurance focuses more on process control during production. In this respect, quality assurance means quality management of processes and is directed as much toward the internal organization of each participant and to the interfaces between them. The purpose of this change is the **reduction of failure cost** due to deficiencies in the project.

Contrary to most other industries, the construction industry usually operates at temporary locations. This requires the development of

procedures for each particular project. In this context the quality system in the construction industry includes two parts (see Fig. 6) (CEB, Bulletin 241 1998):

- The company quality system (permanent)
- The project quality plan and its documentation (case by case)

In other words, the result of a project quality plan is adequate project quality documentation. This includes procedures and instructions developed mainly for the given project. It is apparent that in the following subsections, only reference to the project quality plan and its documentation will be made, since the company quality system is beyond the scope of this entry. At the same time, an effort will be made to adapt the general rules in effect mainly for new structures to seismic retrofitting and strengthening of existing buildings and public works.

Quality Assurance of Assessment Procedures

According to the presentation of section “[Seismic Assessment](#),” assessment procedures may be classified in the following categories:

- Post-earthquake emergency damage inspections
- Post-earthquake assessment
- Pre-earthquake assessment

The above activities have nothing to do with building production procedures as they are services. However, the quality of assessments influences decisions in regard to retrofitting and therefore the performance of buildings or similar works in future earthquakes.

The detailed assessment of existing structures must be examined together with retrofitting activities, as it constitutes a part of the retrofitting design.

Quality Assurance of Emergency Post-earthquake Inspections

The quality plan of the project (emergency post-earthquake inspections) must refer to the following issues:

- Determination of the affected areas in order to estimate the scale of the operation
- Qualifications of the personnel who will undertake the inspection and evaluation activities at various levels and departments, that is:
 - Personnel for first-level inspection of conventional buildings
 - Personnel for inspection of buildings of special interest (e.g., hospitals, schools, etc.)
 - Personnel for second-level inspections
 - Personnel for third-level inspections
 - Personnel for emergency proppings or demolitions (design–execution)

The qualifications and number of the members of inspection teams, in the case of the earthquake of June 20, 1978, in Thessaloniki and all others in Greece since then are depicted in Fig. 7 (Penelis and Kappos 1997).

- Personnel resources. It is very important for the whole operation to ensure in advance the personnel that will be used for the inspections. Public administration, public corporations, and the private sector supply the usual personnel resources (see Figs. 7 and 8) (Penelis and Kappos 1997; Penelis and Penelis 2014).
- Selecting in advance the building for the operational headquarters. This should be a building designed for immediate occupancy (e.g., an existing communications center).
- Specifications of the activities of the headquarters should be clarified in the quality

plan of emergency inspection and the relevant documentation, that is:

- Coordination with other services charged with the disaster relief
- Mobilization of the personnel for inspections and distribution of these personnel to local inspection centers
- Coordination of the activities of local inspection centers
- Determination of the position of the local inspection centers in a city or a district
- Distribution of inspection personnel depending on qualifications into first-level teams, second-level teams, committees for checking buildings of special interest, etc.
- Central management of all materials and equipment needed for the inspection teams such as inspection forms, measuring tapes, hammers, chisels, flashlights, batteries, etc.
- Organizing brief training courses on damage assessment for inspection personnel
- Provision of summary manuals prepared in advance on seismic pathology, the method of emergency inspections, and the filling in of the inspection forms that the teams are obliged to prepare after each inspection
- Listing of buildings or other works of vital importance for the post-earthquake operation of the area which must be inspected first by highly qualified structural engineers

The responsibility for the preparation of the quality plan and the relevant quality documentation belongs to the “Governmental Emergency Management Agency,” which should prepare, in cooperation with local authorities, quality plans for all districts of high seismicity of a country.

The key to the success of the above plan of operations is the personnel:

- They must all be at least civil engineers with ascending qualifications in structural engineering and long experience in higher-level inspections and decision-making.
- They must be teams of two persons so that they can cross-check their evaluations.

Retrofitting and Strengthening Measures: Liability and Quality Assurance, Fig. 7 Organizational chart for the inspection service in Thessaloniki after the earthquake

of 20 June 1978 (From Penelis and Kappos (1997) with permission of C.R.C. Press)

R

Quality Assurance of Post-earthquake and Pre-earthquake Assessment

The quality plan and the corresponding documentation must refer to the following issues:

– References and applicable documents

Documents to be used as a source of reference in the procedure shall be listed. The following may be mentioned by way of example:

- Contract documents
- Project specifications
- Standards and guidelines for the assessment procedure (e.g., FEMA 310/1998/ ASCE 31–02 or relevant ministerial decrees at national level)
- Other documents relevant to the procedure (e.g., existing files with drawings and calculations)

Retrofitting and Strengthening Measures: Liability and Quality Assurance, Fig. 8 Organizational chart for the pre-earthquake preparation period according to

ATC3-06 (USA) (From Penelis and Kappos (1997) with permission of C.R.C. Press)

– **Preparation and handling**

- The most important aspects of the evaluation must be condensed in the quality plan, identifying:
- Collection of data and visit to the building or public work
- Determination of the seismicity of the region
- Determination of the level of performance
- The number of quality-related activities (e.g., the three tiers of FEMA 310/ASCE 31-02 standard and the number of the checklists of each tier)
- The checklists that must be used for each activity (e.g., structural checklists, foundation checklists, and nonstructural checklists)

All the above are depicted in the flowchart in Fig. 5 (FEMA 310/1998/ASCE 31-02).

- **Simplified analysis and design verifications at all critical regions of the structural system.**
- **Identifying damages for any reason.**

– **Detailing deficiencies.**

- **Quality control.** This may be carried out by an **independent engineer** or by the **internal audit** of the agency responsible for the evaluation.

Quality Assurance of Detailed Assessment and Retrofitting

General

For a successful structural intervention, coordinated measures are needed in order to ensure quality of design and construction. The detailed assessment is included in the design procedure. In this respect two separate quality plans must be elaborated, the first for the design and the second for the construction. The first is elaborated by the company that is responsible for the design, the second by the contractor. Both project quality plans must be approved by the project manager and then are added to each company's quality system (see Fig. 6) and to the contract with the owner of the building (Fig. 9).

Retrofitting and Strengthening Measures: Liability and Quality Assurance, Fig. 9 Flowchart of quality management procedure of retrofitting activities

Design Quality Plan

Though the design quality plan should be tailored to the particular project, such a plan should include the main phases of the project and address at least the following issues:

– References and applicable documents

Documents to be used as a source of reference in the procedure shall be listed. The following are mentioned by way of example:

- Contract documents
- Project specifications
- Standards and guidelines for the detailed assessment and retrofit design (e.g., FEMA-356/2000/ASCE SEI 41–06 or EC 8–3/2005, National Annexes, etc.)
- Other documents relevant to the procedure (e.g., existing files with drawings and calculations)

– The most important aspects of the detailed assessment and retrofitting design must be condensed in the quality plan identifying such elements as:

- The level of technical data generated by the field investigation, in relation to the **knowledge levels** that will be introduced in the analysis and design and particularly with respect to:

- Geometry
- Details of the structural system
- Materials of the structural system
- The analytical methods to be used to identify and quantify the building response and vulnerabilities
- The structural performance levels or limit states for which the structure shall be assessed and redesigned
- The principles of conceptual design to be followed
- Drawings and documents that should be included in the design study, with particular reference to:
 - Drawings of demolitions
 - Drawings of temporary propping
 - General drawing of retrofit
 - Detail drawings
- and to the following reports:
 - Report of detailed assessment
 - Report of redesign of the rehabilitated structure
 - Technical descriptions of the intervention scheme
 - Technical specifications for materials and works
 - Quantity estimates
 - Bill of quantities
 - Cost estimates

- Testing and inspection plan at construction stage
 - The main phases of the project for which the contractor shall elaborate a method statement and shall submit it to the project manager for approval
- **Quality control of design**
- Seismic retrofitting (repair or strengthening) requires an appropriate scheme of counterchecking of design documents. When the design has been completed, an additional check should be performed by an **independent engineer** providing an independent second opinion (ATC 40–1996). This may be a governmental or private agency responsible for verifying the criteria and checking the calculations, the drawings, and the technical reports, certifying that they conform to the criteria and regulations of the building codes and relevant guidelines. No matter who is financially responsible for quality control (the owner or the designer), this special requirement for a third-party control is incorporated into the quality plan and its documentation.
- **Design review**
- The design files (drawings, technical reports, and calculations) together with the checking of the “independent engineer” are **reviewed** and approved by the project manager of the work (see Fig. 9) before releasing the tender documents for construction bids.
- **Building permit**
- The obligation of the “designer” to get the building permit for the retrofit from the relevant governmental or municipal agency by preparing all necessary documents must be referred to in the quality plan of the project.

Construction Quality Plan

Construction of seismic retrofitting works must be checked for quality and general compliance with the intent of the drawings, technical documents, and specifications of the retrofitting design, via the construction quality plan of the project. As was previously mentioned, this document will be prepared by the contractor and will be checked and approved by the project manager (Fig. 9).

This document should at a minimum include the following:

1. Required contractor quality control procedure including elements such as the following:
 - Materials testing
 - Submission to the project manager of the required quality certificates for industrial materials (e.g., steel reinforcement, FRP laminates, etc.)
 - Temporary propping procedures
 - Demolition procedures
 - Reinforcement detailing
 2. Required “designer’s” services including steps such as the following:
 - Review of required contractor submittals
 - Monitoring of required inspection reports and test results
 - Consultation with the contractor on the intent of the construction documents

The “designer” is either the original designer of the retrofitting design or an associate of the project manager of the work with the proper qualifications.
 3. The main phases of the project for which the contractor shall elaborate and submit method statements to the project manager for approval
- The designer shall be responsible for performing periodic structural observation of the retrofitting works at significant stages of construction like temporary propping, demolitions, reinforcements, details, etc. This procedure should be in addition to any special **inspection and testing**.

The project manager of the work shall engage on behalf of the owner the services of a special inspector to observe construction and prepare **quality records and nonconformity and corrective action reports**.

The above inspector shall be responsible for verifying the special test requirements as described in the construction quality plan.

The standard FEMA-356/2000/IASCE SEI 41–06 introduces a strong involvement of the Code Official, that is, the governmental or municipal agency for permits for the quality control of design and construction of seismic retrofitting.

Liability

General

When, despite the existing quality assurance system, deficiencies occur, then liability issues arise. Some legal terms will be briefly clarified below since they will be used in the discussion that follows.

Liability is one of the most significant terms in the field of law since it describes the condition of being actually or potentially subject to a legal obligation. Liability may be **criminal** or **civil**.

The basic assumption in **criminal liability** is that there is both a “mental element” and a “physical element” to the offense. It should be noted that various offenses in relation to, for example, traffic law or environmental law have been so structured that the “mental element” is in fact not required for a conviction. In this category are also classified offenses in violation of building law. These offenses are not characterized as **crimes** but rather as **misdemeanors** and are basically related to “**negligence**.”

Civil liability gives a person rights to obtain redress from another person, e.g., the ability to sue for damages or for personnel injury. For there to be an award of damages, the injured party has to have suffered an actual loss, be it personal injury, damage to property, or financial loss. The burden of proof is “the balance of probability,” which is much lower than for criminal matters.

Professional indemnity insurance is the kind of insurance that protects the insured from claims by dissatisfied clients in disputes over errors. The most usual claims involve:

- Negligence
- Intellectual property
- Loss of documents/data
- Dishonesty
- Breach of duty
- Defective products

In this respect **professional indemnity insurance** can cover mainly **civil liabilities** owing to **professional negligence**.

Liability for Buildings and Civil Engineering Works in Criminal Law

Most European countries have incorporated into their Penal Law articles against the violation of the rules of building.

For example, Greek Penal Law stipulates the following:

“Anybody who violates by probable intention or negligence the commonly accepted technical rules during the design, management, or execution of buildings or public works or a demolition, thus putting at risk the life or health of persons, is punishable for up to 2 years in prison.”

Similar stipulations are also met with in the penal codes of other European Countries. According to the above stipulation, the person responsible for the violation of the law may be:

- The designer
- The manager of the building or civil engineering work
- The contractor who executes the work or the owner if he executes the works using employees

Bearing in mind that during design and construction of large-scale projects, each of the above “responsibilities” corresponds to a large number of persons, the law gives the judge the discretion to distribute liabilities based on the evidence of witnesses and existing documents.

According to the law, liability arises in the case of **violation of the commonly accepted technical rules**. These rules comprise presidential decrees related to building activities, codes of practice, standards, technical specifications, etc. A basic parameter for the judgment is the elaboration of **expert evidence**, which the court solicits from an independent expert.

A basic parameter for a conviction is the objective justification of the risk of life or health and the evidence of causality between violation of building rules and damage. In practice it is very difficult for the judge to justify a conviction without any injury or death in the work. It should be noted that in the case of death or injury, the article of criminal liability in building works is combined cumulatively with the

relevant article of Penal Law for death or injury **owed to criminal negligence**.

Liability for Buildings and Civil Engineering Works in Civil Law

Liability for building works is included in the **tortious liability** provisions of the civil code of each country. Similarly, in the EU the Product Liability Directive 85/374/EEC of 25 July 1985 has established for EU countries legislation regarding **strict product liability** for damage arising from defective products. This liability is in addition to any existing rights that consumers enjoy under domestic law.

Strict liability applied to product liability suits makes a manufacturer or seller responsible for all product defects and particularly **design defects, manufacturing defects, and defects in marketing**. Strict liability wrongs do not depend on the degree of carefulness of the defendant. This means that the defendant is liable when it is shown that the product is defective and the product has caused harm to the consumer.

The term “**product**” in the above directive refers to **movable** personal property. In the corresponding US law, it refers to **tangible** personal property, and in this respect the relevant law in the USA may also extend to the products of the building industry. The above directive must be related to Directive 89/106/EEC, which refers to the technical characteristics particularly of the **construction products** which are incorporated into buildings or public works. In fact, the Council of the EU, recognizing the significance of building materials and of building procedures for the protection of persons and property, has established Directive 89/106/EEC of 21 December 1988. This is a **performance-oriented** directive, since technical characteristics of the “**construction products**” are influenced by the performance-based six essential requirements for the works, namely:

- Mechanical resistance and stability
- Safety in case of fire
- Hygiene, health, and the environment
- Safety in use

- Protection against noise
- Energy economy and heat retention

European codes, standards, and technical approvals are the consequence of the above directive, and in this respect also of [EC8-3/2005](#), which applies to the detailed seismic assessment and retrofitting of buildings.

In other words, particularly for “**construction products**” and building or civil works, the EU has established a very strict system for quality assurance (codes, standards, etc.). Thus, in case of defects in the works, a causality between defects and code violation can be easily found and liabilities may be determined and justified.

Liability for Retrofitting and Strengthening of Buildings or Public Works

It is apparent that this type of liability lies within the bounds described above of criminal and civil liability for construction products and buildings or civil engineering works.

However, a distinction should be made here between seismic assessment (section “[Seismic Assessment](#)”) and detailed seismic assessment and retrofitting (section “[Detailed Seismic Assessment and Retrofitting](#)”), since these two main activities differ drastically.

Liability for Seismic Assessment

Emergency seismic inspections and assessment procedures are conducted under the pressure of time and cost as they involve thousands of buildings and public works. In particular, emergency inspections are conducted in emergency situations. Therefore, the engineers are not able to use their main scientific tools, that is, on-site measurements, laboratory tests, and analysis. In this respect it is the author’s opinion that the assessment personnel should not be held personally **liable** for any damage that may occur to persons and property as a result of any act or omission in engineers carrying out their duties during emergency inspections. Otherwise, the personnel becomes very conservative and the damage findings of the assessment appear to be much more extensive than the reality. The case of the Kozani earthquake in Greece (1996) is

characteristic, where at the first-level inspection 90 % of the schools of the region were found to be “red” (extended structural damage), while at a second-level inspection these were limited to only 10 % “red” and 15 % “yellow.” For the time being, existing legislation in EU countries does not make any reference to this issue, leaving the application of the tortious liability provisions to the discretion of the judge.

It is important to note here that in US Presidential Executive Order 12941/1-12-94 (1994) for “**Seismic Safety of Existing Federally Owned or Leased Buildings**,” where the assessment procedure for the above building is specified, it is explicitly stated that: “Nothing in this order is intended to create any right to administrative or judicial review, or any other right, benefit or trust responsibility, substantive or procedural, enforceable at law by any party against the U.S., its agencies or instrumentalities, its officers or employees or any person.” In other words, this paragraph of the above Executive Order releases anybody involved in the assessment procedure from any liability, civil or criminal.

Liability for Detailed Seismic Assessment and Retrofitting

As presented in section “[Detailed Seismic Assessment and Retrofitting](#),” this activity includes:

- Detailed assessment
- Design
- Execution of work

In this respect it is an activity similar to that for a new building or civil engineering work. Therefore, the legislation for liability applying to new buildings or civil engineering works also applies to seismic retrofitting and strengthening.

Summary

This chapter deals with the steps of procedure for seismic retrofitting and strengthening of buildings and civil works. The quality assurance

mechanisms applied at each step of the retrofitting procedure are also outlined in a detailed fashion. Finally the liabilities emerging in case of defects or failures are outlined and described so that the practicing engineers as well as the relevant authorities can evaluate their significance, during crisis design making.

Introduction

Contemporary Structures, Seismic Retrofit, and Strengthening

A variety of materials have emerged into the retrofit and strengthening field. Interdisciplinary approaches in material's science, in structural retrofit, and in earthquake engineering have better addressed unidentified gaps in knowledge. Growing interlinks among industry, researchers, and practitioners favor introduction of advanced materials per different kinds of structure, application, and retrofit technique. Modern retrofit design combines different materials utilizing their unique attributes (physical properties, mechanical as well as time- and loading type-

dependent behavior and durability-related properties *fib* Model Code 2010, *fib* 14, ACI440-08) toward optimized performance of the structure as a whole.

This chapter presents the materials used for the seismic retrofit of structures covered by modern retrofit design codes and recommendations such as reinforced concrete, steel, and composite structures as well as masonry structures (EC8-3 2005; FEMA 547 2006; Fardis 2009; CNR-DT 200/2004). It discusses materials for both repair and strengthening of contemporary structures with special focus on reinforced concrete buildings and bridges (Priestley et al. 1996; Fardis 2009) as well as on advanced materials (high-performance cement-based materials, shape-memory alloys, fiber-reinforced polymers, textile-reinforced mortars, etc.).

Jackets made of concrete and reinforcing steel as well as repair mortars have been widely used in the retrofit of structures for many decades. In the 1960s strengthening of concrete structures included the emerging technique of structural steel plates bonded to the surface of the tension zone with adhesives and bolts. Further, the use of fiber-reinforced polymers (FRPs) has been established in construction in the late 1980s, and they have been increasingly used ever since (TR 55 2012). Specifically, FRPs were firstly used in Europe and in Japan, while their use was adopted in the United States and Canada later on (Bank 2006). FRP systems and applications focused on seismic retrofit and strengthening were developed by the Japanese, while United States followed in the early 1990s. Today a wider variety of retrofit and strengthening material exist including injective resins, polymeric mortars, fiber-reinforced concrete, nonmetallic reinforcements, and even nanoenriched materials, and their availability has broadened remarkably the options of practitioners. Application performance-based approaches and standards for the design, application, and quality control of materials used have raised retrofit efficiency, reliability, and safety. Earthquake-resistant repair and strengthening requires advanced performance of added materials as they usually need to resist extreme stresses, together with the

elements of the existing structure, to ensure collapse prevention and avoid human loss.

In what follows common materials used in retrofit and strengthening of structures are presented. They are classified according to the nature of their basic constituent.

Retrofit and Strengthening Materials

Concrete and Cement-Based Materials

Cast-in-place ordinary concrete, fiber-reinforced concrete, shotcrete or gunite, self-consolidated concrete, and advanced mortars (polymeric or fiber enriched) comprise a class of materials widely used for the purpose of retrofit and strengthening of existing structures. Most of these materials serve as the matrix for metallic reinforcements to form external retrofitting or strengthening jackets or for the repair of damaged concrete members. Advanced mortars may be used as matrix for nonmetallic reinforcement (mainly textiles) in jacketing. Advanced fiber-reinforced concretes or mortars (with steel, polymeric, carbon, glass, natural, or other discontinuous fibers) may be used as sole strengthening systems. Repair patches, mortars, and cement grouts are used in damaged concrete and masonry members. Special materials of the category may be used as protective finishing. All materials of this class should ensure adequate bond with existing old concrete surface in bond-critical applications. The added concretes and mortars may contain appropriate fibers (steel, polypropylene, PVA, etc.), constituents, or additives to minimize the effects of shrinkage or creep deformations and prevent the deterioration of the interface bond.

Many advanced cement-based materials are already under consideration for the next generation codes (*fib* Model Code 2010), while most recent and emerging developments in the field (Fardis 2012) are expected to follow.

Concrete Under Earthquake Excitations

Concrete is widely used in retrofit and strengthening of existing structures. Recent developments in cement-based materials are aiming at

offering performance-based solutions per application. The mechanical behavior of concrete is usually considered in a macroscopic level. In this regard, the effect of concrete composition and of its constituents is neglected and is taken as homogeneous continuum. However, concrete is a composite heterogeneous material, as it consists of gravels bonded together with a mixture that consists of cement, sand, and water. A microstructural level approach may reveal the effect of the size, quantity, and properties of the constituents of the concrete on the mechanical behavior of the material at the macroscopic level. The mechanical performance of the concrete depends on the mechanical performance of the gravels, the cement paste, their bond, and their ratio. Specifically, it should be taken into account that extensive bond microcracks exist at the interface between gravels and mortar even before the loading of concrete. Many of the microcracks are caused by segregation, shrinkage, or thermal expansion in the mortar. Further, the cement paste has a high porosity of about 30 % that corresponds to presence of water and/or air. During concrete loading, microcracks are developed (Fig. 1) because of the differences in stiffness between aggregates and the mortar. Consequently, the aggregates/mortar interface becomes the weakest link in the composite material. This is the reason for the low tensile strength of concrete. Moreover, microcracks explain the nonlinear behavior of concrete during loading. Accurate modeling of the behavior of concrete in microstructural level should take into account the abovementioned issues. The effects of partial plasticization and of the fracture of concrete on the inelastic behavior of the material should be considered as well.

In what follows, the concrete is considered from a macroscopic point of view. As already mentioned, ordinary concrete used in jackets possesses a low tensile strength. Thus, from a macroscopic point of view, cracking normal to tensile stresses (even low stresses) is expected. Under inelastic uniaxial compressive loading, concrete elements exhibit a gradual degradation of their elastic modulus due to accumulation of internal damage. This degradation is fairly small

Retrofitting and Strengthening of Contemporary Structures: Materials Used, Fig. 1 Development of microcracks inside concrete during loading

in the pre-peak response but becomes significant in post-peak loading. Moreover, in seismic redesign of concrete structures, low-cycle fatigue effects on concrete under compression are not expected to be important. This is because the duration of strong ground shaking and the predominant periods of common buildings suggest normally a low number of high compressive stress cycles, not more than 10 (Fardis 2009). Thus, the monotonic compressive stress-strain behavior of existing or added concrete may serve as the envelope curve of its cyclic behavior under earthquakes in redesign.

The use of higher-quality concrete in added jackets than the existing ones magnifies the inherent brittleness of the post-peak behavior of the material under uniaxial compression. In concrete

members, transverse reinforcing materials are used to confine and thus restrain adequately lateral expansion of concrete (steel or FRPs, etc.). The concrete is then under triaxial compression, and a significant increase of its strain ductility (and secondly of its strength) takes place (see Fig. 2). The effects from the confinement of concrete are discussed in the sections “[Steel and Metal-Based Materials](#)” and “[Nonmetallic Reinforcements and Resins](#)” of the main confining materials. In general, the monotonic behavior of confined concrete may also serve as the envelope curve of its cyclic behavior. Finally, concrete-to-concrete interface bond may deteriorate under cyclic loading and should be taken carefully into account in the design of bond-critical interfaces.

Retrofitting and Strengthening of Contemporary Structures: Materials Used, Fig. 2 Typical stress–strain behavior of cement-based materials and different concretes plain or confined

Advances in Cement-Based Materials

Recently, a variety of fiber-reinforced cementitious products have been developed and applied in retrofit and strengthening of existing structures. Their main characteristic is the enhancement of the tensile characteristics with respect to ordinary concrete. Ultrahigh-strength fiber-reinforced concrete (UHPFRC) shows an increased tensile strength capacity without pseudo strain hardening. On the other hand, fiber-reinforced cementitious composites (FRCCs) exhibit pseudo strain-hardening tensile characteristics and are divided in two main sub-categories: strain-hardening cementitious composites (SHCC) and high-performance fiber-reinforced cement composites (HPRFRC). SHCC exhibit high tensile deformation at failure, while HPRFRC lie in between SHCC and UHPFRC exhibiting both pseudo strain hardening and increased tensile strength and strain.

The tensile stress of SHCC is relatively low compared to that of UHPFRC, while UHPFRC is superior to SHCC in terms of controlling crack damage. Therefore, SHCC is mainly used for the areas of tension in a flexural member. The SHCC mixture exhibits excellent performance in crack-damage mitigation and energy dissipation.

Thus, it is suitable for seismic-resistant structures and sections subjected to high stress concentrations. Further, HPRFRC exhibits several desirable characteristics as well, such as strain-hardening behavior, formation of multiple fine cracks, increased energy dissipation, and crack-damage tolerance. HPRFRC can also be used to retrofit reinforced concrete structures and to enhance their strength, ductility, and seismic performance. The unique tensile characteristics of HPRFRC can provide an alternative retrofit solution for extensively damaged concrete members in their critical region or in short members. High-ductility fiber-reinforced cementitious composite under tension had replaced the existing concrete core of a column under seismic loading. The overall lateral load-carrying and deformation capacities were improved when compared to the conventional reinforced concrete column specimen. The retrofitted reinforced concrete columns presented better controlled concentrated local damage in the zone of the plastic hinge. Flexural and shear cracks of the concrete, spalling of the cover concrete, buckling of the longitudinal reinforcing bars, and compressive crushing of the concrete were better controlled in the columns with HPRFRC (Cho et al. 2012).

Steel and Metal-Based Materials

This class of materials comprises reinforcing steel, prestressing steel, and structural steel (EC8-3 2005, *fib* Model Code 2010, FEMA 547 2006). The characteristic ductile strain behavior of steel after yielding enables the concrete section to exhibit increased curvature ductility in order to meet the performance-based criteria of modern design (required section curvature ductility or member chord rotation ductility that corresponds to the target structure displacement ductility). Reinforcing steel in the form of ribbed bars and of appropriate class (Eurocodes) or welded fabric is used in concrete jacketing or as near-surface mounted (NSM) reinforcement in primary concrete members (i.e., NSM stainless steel bars, Bournas and Triantafyllou 2009). Modern earthquake-resistant retrofit design requires the use of ribbed bars with characteristic yield strength between 400 and 600 MPa and hardening behavior within specified limits. Also, characteristic strain at maximum stress should be higher than 5 % or 7.5 % strain (see Fig. 3). For high-ductility class, the upper characteristic value of the actual yield strength should not exceed the nominal value by more than 25 % (Eurocodes). Reinforcing steel is also used as transverse reinforcement (stirrups) in retrofit and strengthening. Furthermore, extensively buckled or fractured bars after a severe earthquake may be replaced in damaged members. Steel dowels and hangers may be necessary to ensure force transfer between old and added concrete (see Fig. 4). In this case, the issue of steel weldability needs to be considered. Moreover, steel stud shear connectors may be used for the same reason in cases of reinforced concrete jacketing of steel members.

Prestressing steel (see typical stress–strain diagram in Fig. 3) is used in external tendons (posttensioning) in the form of strands or wires or bundle of monostrands (inside corrugated metal or plastic ducts or inside smooth steel or plastic pipes) in concrete structures.

Structural steel corner angles, plates, and rods may be used as external steel jacketing of concrete members or in retrofit of masonry. Steel jacketing with two half shells welded together

to form a tube with a gap from the existing column, grouted with mortar, is another alternative mainly for bridge piers (Priestley et al. 1996). Structural steel (or aluminum) components may be used in energy dissipative zones of braced frames. Additional steel components may be used in concrete or in steel or in composite steel–concrete buildings. In every case, the characteristics of structural steel should conform to the criteria included in the relevant building codes of practice for steel structures.

Steel Under Earthquake Excitations

Reinforcing steel in external reinforced concrete jackets for the retrofit and strengthening of existing reinforced concrete or steel members comes mainly in the form of bars. Usually, the stress–strain behavior under tension–compression is crucial to assess the longitudinal bars' contribution. The stress–strain behavior under tension is of interest for the transverse reinforcement (stirrups). Steel dowels and stud shear connectors may involve shear (or tensile) behavior of steel- or bond-related issues. External steel plates may be considered under multiaxial loading (i.e., in cases of shear strengthening in order to estimate their yield stress). Bond-related issues may concern bar–concrete interfaces, bar–resin–concrete interfaces (NSM applications), or plate–resin–concrete interfaces under cyclic loading.

As far as the longitudinal bars are concerned, the modeling of their stress–strain behavior requires simple one-dimension elements. Yet, the reinforcing steel exhibits varying stress–strain behavior under cyclic tension–compression with respect to the type of the concrete member, the position inside the section of the member, and the type of the connection between existing member and added jacket (chemical bond, steel dowels, or steel hangers). Also, existing reinforced concrete members usually have inadequate anti-buckling detailing of bars. In existing concrete members subjected to seismic loading, bars normally yield in tension before they do so in compression. Buckling usually takes place during σ - ε branch of unloading from tension to compression that exhibits the

Retrofitting and Strengthening of Contemporary Structures: Materials Used, Fig. 3 Typical stress-strain curves of steel reinforcements and cured FRP sheets

Retrofitting and Strengthening of Contemporary Structures: Materials Used, Fig. 4 Details of jacket with dowels and hangers (Adapted from Tsakiris et al. 2012)

Bauschinger effect (gradual deviation of the tangent modulus of elasticity from linearity – before yield stress – to zero modulus value, after the first yield plateau) or the hardening branch that follows it (Fardis 2009). Buckling of bars depends on the lateral restraint by the transverse steel and the concrete cover, the flexural crack opening, the interaction with dilating concrete core, etc. Notice typical stress–strain diagram of slender bar under compression with stirrup spacing to bar diameter ratio 12 in Fig. 3. Concrete jackets may prevent premature buckling of old bars in the existing columns, but considerations remain for the bars of the jackets.

Typically, beams or columns with low axial compression exhibit predominantly tensile yielding. Therefore, the monotonic curve provides a reasonable envelope to the cyclic response in the tension range, while compressive behavior deviates. In columns with high compression stress levels and high confinement ratios, reinforcing bars may be subject to strain reversals of almost equal magnitude. In that case the stress level for a given strain may substantially exceed the stress indicated by the monotonic behavior (Priestley et al. 1996).

Concrete confinement by steel increases remarkably stress and especially strain of concrete at failure. Notice in Fig. 2 typical stress–strain curves for concrete confined externally with steel spiral. Further, it favors the force transfer between existing column and concrete jackets. Adequate compressive strain ductility of concrete ensures the success of the performance-based redesign in the member level. In general, the monotonic behavior of confined concrete may also serve as the envelope curve of its cyclic behavior with the stipulation that the issues raised for the longitudinal bars' buckling as well as force transfer issues through interfaces and strain gradient in sections subjected to cyclic bending are accounted for.

Recent Advances in Metal-Based Materials

The use of shape-memory alloy (SMA) reinforcements is very promising in retrofit and strengthening of existing structures. SMAs have more than one crystal structure. This is called polymorphism. The prevailing crystal structure or phase in polycrystalline metals depends on both temperature and external stress. They are a class of metallic alloys that can “remember” their initial geometry during transformations (forward and reverse) between two main phases at their atomic level (austenite and martensite).

SMAs include copper–zinc–aluminum, copper–aluminum–nickel, and nickel–titanium (NiTi) alloys. NiTi alloys exhibit better mechanical properties than copper-based SMAs which were first developed in the early 1960s. SMAs have been widely used in retrofit and strengthening projects in the field of damping, active vibration control, and prestressing or posttensioning of structures with fibers and tendons, while recently, iron-based SMAs were developed that can reduce the cost.

Among several recent advances, NiTi SMA wires have been pretensioned before application and then wrapped around a concrete column as external confining reinforcement while being at the martensite phase. Then, by raising the temperature of the wire, transformation to the austenite phase takes place. In this manner, the wire recovers its original shape, and stresses are

imposed by the wire to the concrete core. The effects of active confinement through SMA were investigated analytically on a RC bridge column retrofitted with SMA spirals. The behavior of the column was studied under cyclic loading and earthquake excitations. Active confinement improved the seismic behavior of the columns in terms of strength, effective stiffness, and residual drifts. Early increase in concrete strength associated with using active confinement delayed the damage experienced by both concrete and steel (Andrawes et al. 2010).

Active confinement, and its subsequent beneficial effects, has also been achieved by means of prestressed metal strips. Recently, posttensioned metal straps were used to retrofit a full-scale reinforced concrete structure tested in shake table (Garcia et al. 2014). Also, unbonded high-strength steel wire was used to passively confine concrete cylinders. Typical curves for prestressed straps or high-strength wire spirals are illustrated in Fig. 2.

Nonmetallic Reinforcements and Resins

Nonmetallic reinforcements consist of continuous organic or inorganic fibers, embedded in a matrix (*fib* Model Code 2010). Fiber-reinforced polymers (FRPs) are nonmetallic reinforcing fibers embedded in a polymeric matrix. Typical fibers have relatively high strength and high modulus of elasticity. The polymer transfers the load among the fibers and protects them against abrasion or aggressive environments. The polymeric matrix has relatively low strength and low modulus of elasticity. The most common resin systems used in FRPs for structural applications are the thermosetting epoxy and vinylester polymers. The glass transition temperature, T_g , of the impregnating polymers (typically far lower than the corresponding resistance at elevated temperatures of the fibers) and of the bonding adhesives is of great importance. T_g of the polymer controls the performance of the FRP system as a whole, at elevated temperature, especially in bond-critical applications. After T_g temperature the polymer falls into a plastic state, it softens, and the mechanical properties degrade (especially the flexural and bond strength of the FRP are affected).

Principal fibers are made of carbon, glass, and aramid (*fib* 14 2001). Recently, basalt (inorganic fibers) and PBO (polyphenylene benzobisoxazole) FRPs are used in retrofit and strengthening applications (Hollaway and Teng 2008; *fib* Model Code 2010) as well as PEN and PET FRPs. Other interesting emerging thermoplastic fibers are ultrahigh-molecular-weight (UHMW) polyethylene fibers and polyvinyl alcohol (PVA) fibers for FRP bars and FRP sheets (Bank 2006). Most of them present linear elastic behavior up to failure (see typical curves of different cured FRPs in Fig. 3), while some present divergence from linearity (bilinear behavior for PET, PEN). Different carbon fibers exhibit modulus of elasticity ranging between 215 and 800 GPa, tensile strength between 1,800 and 6,000 MPa, and ultimate strain between 0.20 % and 2.30 %. Aramid fibers have modulus of elasticity ranging between 70 GPa and 130 GPa, tensile strength between 2,750 and 4,100 MPa, and ultimate strain between 2.40 and 5.00 %. Common glass fibers (high electrical resistance) in retrofit and strengthening are subdivided in E-glass, S-glass (stronger and stiffer than E-glass), and alkali-resistant (AR) glass. Glass fibers have modulus of elasticity ranging between 70 and 90 GPa, tensile strength between 1,900 and 4,800 MPa, and ultimate strain between 3.00 % and 5.70 % (*fib* 14 2001; Hollaway and Teng 2008). The mechanical properties of basalt fibers range between 89 and 95 GPa for the modulus of elasticity, between 3,000 and 4,900 MPa for the tensile strength and between 3.00 % and 5.00 % for the ultimate strain. The mechanical properties of different reinforcing fibers are gathered in Table 1. The mechanical properties of the FRP (fibers and polymer) depend on the fiber volume fraction, the orientation of the fiber, the method of manufacture, the temperature and duration of the cure cycle, and the age of the polymer composite (Hollaway and Teng 2008). The fiber volume fraction in most FRP bars is estimated between 50 % and 60 % and for FRP strips between 60 % and 70 % (Bank 2006). Carbon FRP systems present high resistance to alkalinity/acidity exposure and to creep rupture and fatigue. Glass FRP systems present thermal expansion coefficient similar to concrete. Glass and aramid FRPs are excellent insulators and

Retrofitting and Strengthening of Contemporary Structures: Materials Used, Table 1 Typical mechanical properties of reinforcing fibers

		Modulus of elasticity (GPa)	Tensile strength (MPa)	Ultimate strain
Fibers	Carbon fiber	215–300	3,500–6,000	0.015–0.023
	High modulus carbon	370	3,500–4,410	0.0095–0.012
	Ultrahigh modulus carbon	570–800	1,800–2,300	0.002–0.0166
	Glass	70–90	1,900–4,800	0.03–0.057
	Aramid	70–130	2,750–4,100	0.024–0.05
	Basalt	89–95	3,000–4,900	0.03–0.05
	PBO	270	5,200–5,400	0.01–0.02
	PEN	22–27	790–1,030	0.045–0.05
	PET	6.7–18	740–920	0.07–0.138
	Vinylon	16	735	0.046
	Polypropylene	2	400	0.20
	UHMW polyethylene	175	2,400	0.019

present high impact tolerance. Basalt fibers are derived from volcanic deposits in a single-melt process. They offer better thermal stability, heat and sound insulation properties, vibration resistance, as well as durability than glass fibers.

FRPs in retrofit and strengthening are met in the form of pre-cured bars and laminates as near-surface mounted (NSM) reinforcement. FRP tendons are used in external posttensioning. They are often applied without duct. FRP strips, laminates, profiles, sheets or fabrics, and filaments are used as externally bonded reinforcements. FRP sheets or fabrics are applied by wet layup or pre-impregnated (prepreg). FRP prestressing systems have been developed in the form of wires, strands, bars, or plates. Various different nonmetallic reinforcing elements are shown in Fig. 5. Design recommendations and codes include the use of FRPs for static and some of them for seismic actions (*fib* Model Code 2010; *fib* 14 2001; JSCE 2001; ACI440-08 2008; CSA S6-06 2006; *fib* 24 2003; CNR-DT 200/2004 2004; TR55 2012 among else). Furthermore, FRP grids and fabrics may be embedded in shotcrete or mortar jackets.

The aforementioned FRP products concern mainly reinforced concrete structures. Yet, carbon FRP plates (with or without prestress) and wraps have been widely used for the retrofit and strengthening of steel structures (increase of member and connection structural capacity,

fatigue crack control, relieve of permanent stresses, corrosion protection). Furthermore, carbon, glass, and aramid FRP plates, grids, and sheets or glass FRP bars (NSM or internal) have been widely used for the retrofit and strengthening of masonry structures (walls, piers, arches, and vaults), bonded with epoxy or cement-based materials. Finally, carbon and glass FRPs have been used in timber structures since the 1960s (Hollaway and Teng 2008).

Different types of resins (mainly epoxy based) are used widely in concrete repair as injected resins for capillary cracks or cracks with higher width or as protective coatings.

Nonmetallic Materials Under Earthquake Excitations

The early systematic research by Priestley et al. (1996) and Seible et al. (1997) in FRP-retrofitted reinforced concrete columns has served as a solid basis for further seismic retrofit developments. Also, it revealed some of the key features of the use of FRPs over conventional techniques. As already discussed, FRPs possess high tensile strength as well as tensile modulus of elasticity and tensile strain at failure that varies among different materials. FRP jacketing has been proven to be a very advantageous alternative to reinforced concrete jackets or steel jackets or steel caging for the following cases of local seismic strengthening of existing concrete members (within certain

Retrofitting and Strengthening of Contemporary Structures: Materials Used, Fig. 5 Different reinforcing fibers and FRPs: (a) unidirectional carbon, glass, and aramid fiber sheet, (b) transparent bidirectional glass FRP sheet after curing, (c) basalt fiber sheet, (d)

fractured glass FRP confining jacket, (e) carbon FRP tendons, (f) carbon FRP laminate, (g) carbon FRP strip for near-surface mounting (NSM), (h) carbon FRP bars, (i) glass FRP bars, (j) polypropylene fiber rope, (k) nylon rope

case-dependent limits): (a) enhancement of the compressive axial strain ductility of concrete through confinement (transverse fiber reinforcement), (b) delay of the premature buckling of the longitudinal steel bars through confinement, (c) upgrade of inadequate lap splices of longitudinal steel bars through confinement, and (d) enhancement of the shear capacity with externally bonded FRPs (transverse fiber reinforcement). In all the above cases, FRPs provide adequate lateral restriction against evolution of undesirable concrete cracking through their unique elastic tensile behavior up to failure. That is, if the flexural capacity of the member (mainly column or wall) is adequate in redesign, then FRPs can prevent brittle shear failure of concrete and loss of bond between steel lap-spliced bars and concrete, in order to develop their full tensile yield stress. They can enhance slender bars in order to develop adequate compressive stress. Having suppressed the abovementioned premature failures and by enabling increased compressive concrete strains, the member can meet the section curvature ductility and the corresponding member deformation

requirements of redesign. FRP shear strengthening of beams or of external beam–column joints or repair of damaged ones with injective resins is also an alternative – within certain limits in any case. In all the above cases, the FRP reinforcement is exposed primarily to variable cyclic tensile deformation in the direction of its fibers, through the polymer–concrete interface. Furthermore, FRP is under compression through its bond with concrete interface. Compression is mainly sustained by the polymer matrix that should maintain its integrity to favor the performance of the tensioned fibers. Seismic flexural strengthening requires the FRP jacket to go through the beam–column connection. Besides, fibers along the axis of the member and under compression require special detailing. Generally, their contribution is neglected, while local buckling should be prevented. Thus, most of the guidelines do not refer to seismic FRP flexural strengthening (EN1998-3) or prevent flexural FRPs when under compression because of cyclic flexure or accidental actions if no measures for local buckling are taken. CNR-DT 200/2004 also includes seismic

FRP flexural strengthening with provisions on anchorage of FRP and proper confinement to avoid fiber delamination and concrete spalling under cyclic loads. In most cases, the use of FRP concerns local seismic retrofit and strengthening as transverse reinforcement. The increase of existing members' sections and of their elastic stiffness because of the use of FRP jackets in these cases is negligible. Thus, FRPs can be applied locally without affecting the distribution of the developed internal forces within the existing three-dimensional structure and can provide structure with significant ductility. Usually, seismic strengthening of existing structures requires also horizontal displacement control through added stiffness or strength enhancement. Therefore FRPs are used in combination with other materials and intervention techniques at a global level (reinforced concrete jackets, new reinforced concrete walls, etc.). Furthermore, heavily damaged reinforced concrete walls (under lateral load reversals) can be retrofitted with properly designed and anchored FRPs to achieve enhanced flexural and shear capacity (Antoniades et al. 2007). Finally, FRP jackets have been proven an effective measure of repair for corrosion-damaged columns (Pantazopoulou et al. 2001).

In general, the discussion for steel-confined concrete and the behavior of bars under earthquake excitations is valid for FRP-confined reinforced concrete as well. However, while ordinary steel transverse reinforcement can only provide a reduced lateral restraint to the dilating concrete after yielding, concrete confinement by FRP increases remarkably stress and especially strain of concrete at failure. This is because FRPs exhibit a linear elastic tensile behavior up to their failure. Therefore, contrary to steel confinement, FRPs exert an ever-increasing lateral stress up to their failure and may restrict, alter, or even prevent concrete dilation up to failure. In general, the monotonic behavior of FRP-confined concrete may also serve as the envelope curve of its cyclic behavior (Rousakis et al. 2008 among others), having in mind mainly the issues raised for the longitudinal bars' buckling as well as force transfer issues through laps and strain gradient in sections subjected to cyclic bending.

Advantages of Nonmetallic Reinforcements over Conventional Retrofit and Strengthening

The main advantages of FRP reinforcements that favor their increasing use over conventional materials in common seismic retrofitting are (e.g., *fib* 14 2001; Hollaway and Teng 2008; Fardis 2009 among others):

- (a) High strength-to-weight ratio. This leads to structural jacket with a negligible added thickness to the original section. It does not add significant additional dead load to the structure and thus does not increase load bearing demands. It enables for selective local (or global) interventions without adding uncertainties or altering the distribution of internal forces in the structure. It maximizes the net floor plan area when applied to vertical members.
- (b) Continuous and flexible structural fibers impregnated and bonded with polymers in situ. In combination with (a) it provides an easy to handle reinforcement that can follow the form and shape of the existing members. It can be used in multiple layers, in different directions to satisfy design needs and form a composite reinforcement after resin curing. Polymer-bonded jacket allows for direct and full strain compatibility all over the jacket surface and increases the effectiveness in bond-critical applications. It allows for easy laps and self-anchoring. Continuous fibers lead to the minimum material waste during installation:
- (c) Compatibility with other retrofitting techniques in cases of combined intervention.
- (d) FRP is a low-maintenance material and can be used to halt corrosion in existing members.
- (e) Immunity to corrosion of the FRP itself.
- (f) All above advantages may lead to minimized disruption of use during installation, minimized labor, and other costs.

Furthermore, FRPs may be unique solution in special cases of demanding interventions such as fully reversible ones or when transparency of substrate should be maximized. Finally, special design requirements may oblige for the

use of specific FRP systems because of their unique physical properties.

Recent Advances in Nonmetallic Reinforcements and Resins

Numerous novel nonmetallic materials have been employed in seismic retrofit and strengthening of concrete members combining different technologies and desirable properties and mechanisms (Fardis 2012). Advanced polymer-modified cement-based mortars have been used as matrix for textiles (TRM, textile-reinforced mortars) offering significant structural capacity upgrade and resistance at elevated temperature (Fardis 2009 among others). Recently, TRMs have been used as confining reinforcement in columns together with stainless steel or FRP near-surface mounted (NSM) flexural strengthening. Significant flexural strengthening under seismic loading was achieved by NSM or externally bonded longitudinal FRPs, provided proper confinement with FRP or TRM jackets that may prevent local buckling of compressed longitudinal FRP (Bournas and Triantafillou 2009 among others).

Another issue of concern is the fire performance of FRPs. Upgraded fire resistance of NSM FRP flexural strengthening applications in beams loaded up to their service load could be achieved. The strengthened beams had proper insulation systems and detailing to improve the performance of the polymer adhesive or expansive mortar was used as bond adhesive (Palmieri et al. 2013). Other applications utilize heat-resistant polymer matrices to enhance the performance of FRP reinforcements.

Active confinement with FRPs (filament, straps, or composite shells) is a viable alternative to metal ones as presented in numerous applications. Beneficial effects of unbonded prestressed FRPs on shear strengthening of beams have been identified also in Lees et al. (2002).

Recently, high-deformability materials (PEN, PET, vinylon, polypropylene, etc.) were explored as transverse reinforcement in seismic strengthening of columns. They were used as reinforcing fibers of FRPs to upgrade the axial strain ductility of concrete columns under axial or seismic loading (Anggawidjaja et al. 2006; Dai et al. 2011).

Other applications concerned external confinement of columns with high-deformability continuous fiber ropes or tapes that were unbonded and non-impregnated (“green” perspective). The tapes and ropes were used alone or in combination with FRPs as passive (Rousakis et al. 2014) or active confinement (Rousakis and Tourtouras 2014). Vinylon and polypropylene ropes are presented in Fig. 5j, k. Furthermore, multiwall carbon nanotubes (MWCNTs in Fig. 6) have been used to enrich epoxy resins used for glass fiber sheet impregnation or as injected resins in concrete crack repair (Rousakis et al. 2014). The use of CNTs in resins raises not only their mechanical properties but is expected to upgrade their temperature resistance as well.

Summary

The chapter presents the main materials used in retrofit and strengthening of contemporary structures. The materials that are already incorporated in design recommendations and design codes are the core of the presentation. Recent advances are also discussed in order to identify the main trends, urgent needs, and potential future emerging materials. The materials of the chapter mainly concern the retrofit and strengthening of reinforced concrete structures such as buildings and bridges, while references to existing structures made of other materials are available. The materials are classified according to the technology of their basic constituent. The three main material classes reviewed in this entry include concrete and cement-based materials, steel and metal-based material, and nonmetallic reinforcements. The chapter presents the basic properties of the materials and their performance in retrofit and strengthening applications with respect to the different techniques and scopes of use in design. The discussion is focused on mechanical behavior, interaction with other existing materials, and open issues from a materials’ point of view to ease the understanding of chapters to follow. The variety of different materials available reveals a trend toward performance-based solution per specific application (more advantageous than others) in accordance with the

Retrofitting and Strengthening of Contemporary Structures: Materials Used, Fig. 6 Scanning electron microscopy image of the MWCNTs (a). Transmission

electron microscopy image of the nanotube (b) (Adapted from Rousakis et al. 2014)

specific design requirements. The basic principles of efficiency, safety, and reliability of retrofit are better served through more specialized materials, as earthquake-resistant structures may have to overcome potential overloads, in order to avoid collapse and human loss.

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions

T. P. Tassios

Department of Structural Engineering –
Reinforced Concrete Laboratory, National
Technical University of Athens (N.T.U.A.),
Zografou, Athens, Greece

Introduction

Preamble

An engineering structure may be partly interpreted as an **organism**, since it comprises various mutually supported members; besides, these members undergo changes in time, due to internal (e.g., corrosion) and/or external causes (e.g., differential settlement). Thus, the way structures are designed, constructed, and maintained could profitably be inspired by scientific branches of medicine applicable to living organisms, such as anatomy, physiology, obstetrics, pediatrics, pathology, surgery, gerontology, etc.

Traditionally, however, structural engineering used to limit its interests only up to a level equivalent to the “birth” of an organism, as if it were supposed to be “invulnerable” (to aging and to environmental effects) and, therefore, “immortal.” Nevertheless, some empirical rules were

developed in time, regarding retrofitting and strengthening of structures damaged due to a variety of causes. Such rules, however, were not always reliably resulting in economical and safe solutions. The need to rationalize these methods of structural intervention became more than apparent during the last decades of the twentieth century.

Thus, structural engineering moved further along the analogy of medical branches to develop new sectors contributing to a better understanding (i) of pathological causes as well as (ii) of the mechanical behavior of damaged regions of structural members.

Historical Background

Still, long before the above discussed relatively recent rationalization of the field, empirical repair of structures has been taken place:

- Some emblematic examples from ancient Greek history show that the need for structural repair and strengthening after various pathological events was deemed essential.

The most emblematic example is perhaps the rehabilitation of the great temple of Zeus at Olympia, after an **earthquake** that damaged the temple during the second century BCE. Professor Dinsmoor (1941) has convincingly proved that at least eight columns located at the NE and the SW corners of the temple were damaged: “A disastrous earthquake left the columns standing, though with their drums jutting outward and inward. The only method of overcoming this irregularity is to dismantle the columns as low down as the root of disturbance and then to rebuild them” (p. 415). And it is very interesting to observe today the construction traces of this huge intervention, although all columns are lying on the ground. Previous milder earthquakes have produced on the same monument dangerous openings of vertical joints between stone elements; their repair was made by means of “hook clamps, placed horizontally across the vertical joint” (p. 405).

Another historical structural intervention is the rehabilitation of the temple of Erechtheion

on the Acropolis of Athens. After a disastrous **fire** (first century BCE), thermal fracturing of several building elements (e.g., a heavy lintel over the north doorway) required their taken down in pieces, and, upon appropriate propping of the overlaying part, their replacement by new ones slid in position. To this aim, grooves were carved on the underlying surfaces, and small diameter iron spheres were interposed to facilitate horizontal sliding of the new lintel into its final desired position (Korres 1997; Caskey et al. 1927):

- After the Second World War, repair and strengthening of **bridges** was intensified. Nevertheless, only traditional materials were used, such as concrete and steel, whereas redesign was based on rather simple calculations.

New materials (such as composite materials, thin steel plates, shotcrete etc.) and new intervention methods (such as seismic isolation, buckling restrained braced systems, etc.) were developed after the 1970s.

The most recent development in the field seems to be the recognition of the importance of the force transfer mechanisms along the old-to-new material interface.

However, it must be admitted that extensive and well-organized efforts in several countries toward preseismic strengthening of existing public buildings were not always materialized: economic and social costs (including occasional shortsightedness) decelerate the process.

Principles of Structural Intervention

In view of the complexity of an actual or a potential seismic damage, structural interventions risk to be ill-conceived (both in terms of safety and economy), unless a **scientific approach** is followed to the extent that available knowledge and data do allow for. To this end, some fundamental rules of broad applicability (“principles”) should be adopted, regarding the three well-known stages, i.e., of assessment, redesign, and construction (repair or strengthening). Thanks to these principles, it is hoped that the entire process of structural intervention will be rationalized, resulting in more safe and economical repair

and strengthening of existing structures, as well as in avoidance of gross errors.

In what follows, several basic principles, to be elaborated later in the text, are briefly introduced:

- **Knowledge first**, action next: The entire bearing system and its possible environmental and man-made damages of an existing structure must be known in detail, before any intervention. The designer should also have a clear knowledge of the pathological causes (and their mechanisms) of existing or potential future damages. Besides, apart from the knowledge of the available resistance to static loads (i.e., strength and stiffness) of structural elements, their ductility capacity should also be known in the case of a seismic intervention.
 - **Consistency to the level of reliability by which action effects and structural capacity are determined**: Poor knowledge of structural properties is not compatible with sophisticated design methods. Similarly, current advanced analytical tools (for the determination of action effects) can only be used when the properties of structural members (e.g., member dimensions) are known within an acceptable level of confidence.
 - The error of “monolithism”: Forces along an “old-to-new” material interface can be mobilized only when a relative displacement occurs along this **interface**.
 - The different **loading histories** of existing and strengthened structural members should be taken into account. In doing so, upon a damaging earthquake, an unloading of the existing element will be considered, whereas added materials for repair or strengthening will remain free of stress until a new earthquake happens.
 - Redesign of existing structures should be carried out with a differentiated target **reliability level**. Consequently, different partial safety factors are usually applied, both for actions and for added materials.
 - Any seismic upgrading of an existing structure is welcome instead of doing nothing, waiting for better future opportunities. This social requirement should however be satisfied in a more or less systematic way, by selecting an appropriate and feasible “**redesign target**” each time.
 - A **conceptual** redesign should precede any quantification of structural intervention measures. Similarly, **maintenance** against environmental effects seems to be the first step of any seismic upgrading.
 - Several intervention strategies are offered, regarding the extent of the intervention (“to the members or to the system”), as well as the question “resistance or ductility upgrading.” An optimization is sought in every case: the multiple costs should be minimized, including the disproportionately high social costs for the relocation of tenants, interruption of professional activities, etc.
 - Repairs or strengthening should contribute toward a uniform distribution of the **margins of safety** along the height of the building under structural retrofitting. Thus, the probability is increased of numerous building elements to dissipate seismic energy, without a disproportionately high ductility to be locally required.
 - Numerous and rapidly developing intervention methods (some of them being rather sophisticated) should be thoroughly known to designers; the traditional schism “**designer/constructor**” does not seem to be promising.
 - Upgrading of monuments against earthquakes necessitates the application of additional principles, because of the possible adverse effects of structural measures against the so-called monumental values, i.e., aesthetics, historicity, etc.
 - The quality of the end product of any technology may equally be jeopardized by deficiencies in conception, in design, in construction, and/or in maintenance. In the field of aseismic structural intervention of existing structures, construction phase is much more subtle and sophisticated than in the case of new structures. Thus, field inspection in this case should be meticulous and well organized; this need should always be recognized.
- Among others, the above “principles” proved to be influential in code development and in

structural engineering practice during the past few decades. Therefore, it is deemed useful to be further elaborated in the remainder of this article.

It is maintained that despite their seemingly theoretical nature, the contents of this article may be of considerable practical importance.

“First Understand, then Withstand”

Preamble

- (a) In the case of **strengthening** of a structure, full knowledge of the existing weaknesses of the structure is needed, before undertaking any intervention. Such knowledge is only feasible if adequate and reliable data is available and properly understood, such as:
- A thorough documentation of the existing structure
 - An appropriate post-elastic analytical model, able (be it in a rough way) to reproduce analytically the observed pathology of the structure
 - Strength, stiffness, and ductility of all structural elements under imposed cyclic actions

A reliable assessment of the structure will then be feasible, and a valid prediction of its behavior under a targeted “design” seismic action can follow.

In the case of simple **repair** of a damaged structure, although certain structural weaknesses may have already been revealed, mapping the complete picture of its structural condition should be pursued. First, an interpretation of the damage morphology is needed in order to understand the failure mechanisms behind it. Second, an estimate of the severity of the seismic actions the structure was exposed to should be reached. Finally, the designer may be obliged to decide if a strengthening is further needed, up to a targeted (design) level of seismic actions, higher than the one that caused the actual damage.

Consequently, for the assessment of structures to be repaired, the data mentioned in the

case of structures to be redesigned (see point (b), here below) need also to be available and well understood:

- (b) After the assessment of its seismic bearing capacity, a structure may be needed to be strengthened. The relevant **redesign** of an existing structure is a distinct process requiring knowledge of further data that should be well understood, such as:
- Appropriate redesign seismic actions
 - Properties of added materials
 - Mechanical behavior of the interface of “existing-to-added” materials
 - Sufficient knowledge of the various available methods of interventions
- (c) In conclusion, a considerably better **understanding** before deciding, before designing, and before constructing is needed in the case of assessment and redesign of a seismic structural intervention, as compared to the case of a new structure. In this regard, certain comments are further included in the following subsections underpinning the general principle “first understand, then withstand.”

“Do Not Trust Magicians”

Several professions may be exercised in the society based on sound experience, without necessarily a deep knowledge of the related phenomena; this may also be the case with empirical design and construction of simple buildings. However, it is unlikely that a safe assessment or a safe and economical seismic strengthening is feasible without a deep theoretical knowledge of several modern branches of structural engineering and substantial subsequent experience. This, one may say, is a matter of professional ethics – but it constitutes a principle of practical importance.

Documenting Is (Part of) Designing

Existing structures, especially buildings, can be viewed as black boxes: a series of important information is frequently missing regarding basic structural data. Thus, documentation constitutes a fundamental part of assessment and redesign, and it should be organized as follows

(see, e.g., Greek Code for Structural Interventions, 2013):

- (a) Data needed for the assessment and the redesign of an existing structure should be systematically collected **separately** for each category, such as structural system and its in-time modification, ground and foundation conditions, environmental conditions affecting durability, geometric data regarding cross sections of bearing and secondary materials, detailing, previous and future uses of the structure and respective loadings, in situ strengths of constitutive materials, previous alterations or damages and their possible previous repair, potential identification of design errors or of construction gross errors, etc.
- (b) The different levels of reliability of data (LRD) should be distinguished, each of them being described in terms of the source and the completeness of available information. Different LRD should be considered for **each** of the basic categories of data needed; e.g., in the case of an existing reinforced concrete (RC) structure, data regarding the geometry of cross sections may be very satisfactory, as opposed to data regarding quantity and quality of reinforcing bars, which is usually less reliable. If this is the case, one cannot consider an “average” LRD; instead, each category of data should be handled in calculations with its appropriate qualification (e.g., EC8-3, Greek Annex)
- (c) Depending on its LRD, **each** category of data should be used in assessment and redesign with possibly different values of partial safety factors (e.g., reduced loading safety factors for dead loads and material safety factors are commonly taken since their LRD level is usually high).

Similarly, the level of sophistication of the adopted methods of analysis should be related to certain minimal reliability levels of input data, in order to avoid the use of inconsistently accurate tools compared to the available data.

Advanced Models of Analysis and Resistance Determination

For the majority of existing seismically vulnerable structures, it is wished that, after a “reasonable” structural intervention and under a critical earthquake, only repairable damage may occur or (at least) collapse will be avoided. Thus, it is expected that several regions of the structure will be found in a post-yield stage. This means that the most appropriate analysis should be **nonlinear**. The use of such analytical models is much more needed in the case of intervention than in the case of new structures. And to this end, typical hysteretic behavior of structural elements should be known.

On the other hand, since (legitimately) several regions of structural members will be in a post-yield stage, their force response behavior should be taken into account in the design, under the following conditions:

- Under a targeted imposed post-yield deformation (in other words, under a certain ductility demand)
- After an expected equivalent number, n , of fully reversed deformations imposed by the earthquake (e.g., $n = 2$), this number being a characteristic of the seismic action itself

In Fig. 1 the hysteretic behavior of a structural element is schematically shown. A force response degradation is obviously taking place under cyclically imposed deformations $\pm \delta$. The most appropriate constitutive law “F, δ ” under seismic actions seems to be the one corresponding to $n = 2$; the so-called envelop (corresponding to $n^+ = 1$) has not much physical sense under cyclic seismic conditions. Real force response for $n = 2$ is considerably lower than for $n = 1$; moreover, available ductilities for $n = 2$ (see Fig. 1b) are very much smaller than for $n^+ = 1$. Thus, seismic design based on “envelops” ($n^+ = 1$) does not seem to be realistic.

In this respect, a couple of other observations need also be made:

- (i) Force response under “negative” imposed deformations in the schematic example of

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions, Fig. 1 Schematic hysteretic behavior (a) and simplified skeleton curves (b), depending on the number of full

reversals “n” and the direction of the imposed deformations (+δ or −δ). Average values of force response and indicative ductility are shown in (c)

Fig. 1 is considerably lower (see in Fig. 1b the curves $n^+ = 2$ and $n^- = 2$). Thus, in most cases average values are used.

- (ii) In the cases where specific values of available ductility factors are used, it is customary to define as “conventional failure deformation” “ δ_u ” the value corresponding to a force response level equal to $\lambda \cdot \max F$ (see Fig. 1c), where the value “ λ ” (< 1) to be selected depends mainly on the acceptable degradation of the element under consideration. Besides, it is expected that, thanks to a **redistribution** of action effects in neighboring structural elements, part of the strength loss $(1 - \lambda) \cdot \max F$ of the damaged element may be undertaken by some neighboring elements. Thus, finally, appropriate “ λ ” values depend on the targeted performance and available ductility of the elements, as well as on the redundancy of the structure. However, only conventional λ values are normally used (ranging from 0.85 for RC and steel structures to as low as 0.70 for masonry structures), without requesting explicit verifications justifying these values in every specific design case.

Causes and Mechanisms of Damage

Damages that appear on the structure after an earthquake constitute a sort of “confession” of the weaknesses of the structure. Correct “reading” of this confession is of paramount importance for the seismic assessment of the structure. To this aim, it is useful to identify elementary failure mechanisms (and corresponding damage morphology) attributed to local forces, such as those presented in Fig. 2 for the case of RC structures. Based on such so to say “vocabulary” of elementary damages, more complex damage patterns due to a combination of effects may be analyzed and better understood. However, **differential diagnosis** may also be needed in order to avoid misinterpretation of causes of damage with similar morphology. Some typical examples of such a case may be (i) a concrete crack along a steel bar due to corrosion, misinterpreted as a local steel-concrete bond failure, and (ii) a diagonal crack in a wall, due to differential settlement, misinterpreted as a seismic damage.

In conclusion, a series of conditions and situations (such as those indicatively shown in this section) should be well understood by the

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions,

Fig. 2 Some indicative elementary failure mechanisms of concrete (“a”) and reinforcing bars (“b”) in the case of RC structural elements may formulate a more complicated “vocabulary,” for a sound interpretation of damage mechanisms

designer prior to any assessment or seismic redesign. Thus, in principle, the level of knowledge needed in the field of structural interventions is considerably higher and more complicated than in designing new structures.

Consistent Level of Reliability

Advancements in engineering are not uniform in all fields; e.g., thanks to the rapid developments in numerical and computational methods, available tools for the analysis of structures are significantly richer and more sophisticated, when compared to available models for resistance determination of critical regions. As a consequence, it may occasionally happen to verify the basic safety inequality

$$E > R \quad (1)$$

in which an action effect “E” is determined by means of, say, a dynamic finite element method, whereas the corresponding capacity (or resistance R) was found by means of a poor empirical method. Such a **difference of reliability** between the two sides of the inequality undermines the desirable rationality of the safety verification sought.

In the case of structural interventions, such an undesirable situation may happen frequently. Sophisticated analytical methods are equally applicable in this case, but the capacity (in terms of forces or deformations) of composite cross sections is not always easily modeled. In fact, capacity is commonly roughly estimated by means of oversimplified empirical methods.

It is therefore needed to formulate the following principle: “In safety verifications, methods of Analysis and methods of capacity/resistance determination should be of comparable reliability”. Regulatory documents should offer more specific rules on this matter.

A similar situation of inconsistent level of accuracy in determining action effects and structural capacity may appear in the case of structural interventions in an **inadequately documented** structure, i.e., when:

- Its geometry is not completely known.
- The strengths of its materials were not directly measured.
- Previous damages and repairs were not identified.

If this is the case, the attempted seismic retrofitting may have doubtful results, despite the apparent “precision” of the calculations used

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions,

Fig. 3 Concrete-to-concrete friction mobilized along a rough interface (after cracking), as a function of the sliding “ s ” normalized by the ultimate sliding “ s_u ” (~ 2 mm for normal concrete) that corresponds to the maximum friction resistance “ τ_u ” under a total normal stress “ σ_c ”

in its redesign. An ensuing principle should be formulated: “Poor documentation is not compatible with sophisticated design methods”.

The Error of “Monolithism”

Some regulatory documents require that, after a seismic structural intervention, “existing and added materials should behave monolithically.” Although (in a qualitative way) this requirement may be understood as a concern for an adequate “collaboration” between two or more different materials, it has however to be reminded that the transfer of shear or tensile forces from the existing (old) to the added (new) material necessitates a certain **local relative displacement** at their **interface**; otherwise, the “reaction” of the added material cannot be mobilized (such local displacements being a “sliding” for shear or a “crack opening” for tensile forces). Consequently, the corresponding constitutive law of structural behavior along the interface should be known, as indicatively shown in Fig. 3 for concrete-to-concrete monotonic friction (Tassios and Vintzileou 1987) or in Fig. 4 for friction resistance under cyclic sliding. By means of such laws, the mobilized forces are calculated as a function of the allowed displacements at the interface, depending on the targeted performance level after the intervention. Thus, the requirement

of “monolithic behavior” should be reformulated as “permissible interface displacement,” resulting in corresponding mobilized resistances of the composite structural element after the intervention.

In this connection, however, the **sensitivity** of the interfaces versus environmental actions should be specifically taken into account: moisture penetration, steel corrosion, and possible aging of composite materials should be appropriately considered.

The Principle of the Loading History Differences

It is important to keep in mind that added materials for repair or strengthening are submitted to quite **different loading histories** than those applied to the materials of existing structural elements. This fact should be correctly taken into account during the pertinent redesign.

Introductory Example

As an **introductory example**, consider the load paths followed in the case of an RC column, before and after a critical earthquake, vis-a-vis those followed during a subsequent intensive earthquake acting on the same column strengthened by means of an RC jacket. Let the existing and the added materials be indicatively

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions, Fig. 4 A formalistic constitutive rule of friction stress response along

a rough concrete-to-concrete interface under cyclically imposed sliding $\pm S_n$, for “n” cycles

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions,

Fig. 5 Force paths: (i) of a RC column before (B) and after (C) seismic damage, during its unloading (A'), at its propping (D) and its seismic reloading (Z); and (ii) of a RC jacket after props' removal (J1) and during its seismic reloading (J2)

considered without any connection along their interface. In Fig. 5, the initially critical “M, N” resistance curve of the existing cross section of the considered RC column is shown. The column (of cross section A_{co}) follows the load path OA

under normal loading and the path AB under seismic loading. At point “B,” damage takes place, and the column is instantaneously unloaded up to a point “C” on the residual resistance curve after damage. After the earthquake,

the representative point moves back to point A ($\equiv A'$), if redistribution of action effects is not considered. At this stage, the structural intervention may be initiated: (i) Propping is installed, introducing a small axial load upwards $N' = -(AD)$. (ii) An appropriate RC jacket is constructed (with a cross section A_{cj}). (iii) After its hardening, props are removed, and their force is transferred to the column (DE) and to the jacket (OJ_1).

In case an earthquake occurs upon redesign, the column will follow the EZ loading path, while the jacket will follow (a different) J_1J_2 loading path, up to their respective critical curves. The total seismic demands taken by the composite element read as:

$$\begin{aligned} \text{Seismically induced axial load } (\Delta N)_E &= N_{EZ} + N_{J_1J_2} \\ \text{Seismic flexural moment } M_E &\succ M_Z + M_{J_2} \end{aligned} \quad (2)$$

Such differences in the loading histories of existent and new material as illustrative by the above example should be appropriately considered in dimensioning the composite element. Ideally, they should also take into account the interaction along the interface between existing and added materials.

New RC Walls

The significance of the subject of differential loading histories in the field of structural interventions is also shown in the important case of **new RC walls**, a posteriori constructed or instilled in a multi-bay RC frame building. The considerable axial force acting on the columns embedded within the new wall does **not** act through the entire wall. Notably, the axial forces carried by the original columns are required to avoid large rocking response of the wall and the corresponding drastic reductions of its effective stiffness.

Nevertheless, during such an almost inevitable rocking of “added” walls, the pole of rotation being located eccentrically, the aforementioned encapsulated columns may be slightly lifted up, so that part of their axial loads to be carried by the entire new wall.

In conclusion, the application of the principle of differential loading necessitates a complete knowledge of the stages of the intervention and of its technical details.

Modified Reliability Level

- (a) Theoretically, in the design of new structures, the selection of an appropriate “target reliability level” depends (i) on the cost of losses in case of failure and (ii) on the cost of safety measures. Normally, the acceptable failure probability P_f corresponds to the minimum of a “generalized” cost function accounting for the design, construction, and maintenance capitalized costs, as well as the cost of all types of losses due to failure, multiplied by P_f . In the specific case of existing structures (provided that their use remains the same in future), the costs of safety measures to upgrade their performance are disproportionately high, compared to the costs of equal safety improvement in the case of a new structure. Consequently, the acceptable failure probability to be chosen in redesigning existing structures is expected to be relatively **higher for the same time of exposure** (see point (b) in section “[Better Do ‘Something than Nothing’](#)”).

Such probabilistic considerations are mainly suitable for the **assessment** of the seismic performance of existing structures, particularly in the case of doubts about design or construction errors, occurrence of exceptional incidents, indications of expiration of the designed service life of the structure, and/or a planned change of its use (see RILEM 2001):

- (b) For ordinary structures (normal occupancy buildings and even normal bridges), the verification with respect to a particular limit state (performance level) is made by means of the **partial safety factor format**. But in the case of existing structures, the representative values of the variables and the values of the partial factors need to be appropriately

modified, in order to meet the reliability requirements discussed in the previous point (a) (see also fib Model Code 2010, Sect. 3.3.3.1).

(c) Redesign of permanent loads.

Characteristic values may be reduced provided that dependable estimation of existing dead loads is available.

Partial factors are usually the same as per new structures, although the inherently lower uncertainty could possibly allow for some reduction of these factors.

Redesign of variable actions:

Characteristic values and partial factors need not be modified, **except** for the following cases:

- If the category of use of the structure is not changed but the frequency of its loading is possibly increased because of the intervention itself.
- Seismic actions (considered as variable actions in regions of moderate or high seismicity) should be appropriately selected for redesign, in accordance with the “something-than-nothing” principle of section “[Better Do ‘Something than Nothing’](#)”. In all cases, however, $\gamma_E = 1$.

(d) Design values of material strength:

(d.1) In the case of force-based redesign (linear methods of analysis in several or nonlinear analysis in case of brittle building elements):

- Existing materials.
 - No additional strength measurements are required. Appropriate “default values” are reduced by partial safety factors used in designing new structures.
 - Appropriate additional strength measurements (mainly in situ) should be carried out at building regions of relatively uniform strength of materials (e.g., tops of columns): (i) resistances of critical **cross sections** are calculated with representative strengths in such building regions (local mean value minus

one standard deviation) and reduced as follows. Conversion factor of concrete strength is not needed; thus, “ γ_i ” may be practically taken equal to 1.30. Values of “ γ_s ” for steel are usually not reduced, unless a strict control of the exact position and diameter of bars is carried out, in which case γ_s may be taken equal to 1.05. (ii) Resistances of large critical volumes of existing RC, appropriately strengthened, may be calculated with mean measured or with default strength values.

- In both cases, for lower levels of reliability of data (see point (c) in section “[Documenting Is \(Part of\) Designing](#)”), further higher partial factors should be used, applicable only for the specifically deficient category of data (e.g., insufficiently known anchorage lengths).

• Added materials.

Normal characteristic strength values and partial safety factors are used. However, in case of added very thin concrete layers or in case of any material added in areas of the structure difficult to inspect, γ_M values may be increased.

(d.2) In the case of deformation-based redesign (nonlinear analysis for quasi-ductile elements or linear analysis with verification carried out by means of the method of local ductility factors “m”):

- Measured or “default” values of strengths of existing materials may be used with their **mean** values for quasi-ductile elements and with partial safety factors equal to unity (unless in case of lower level of reliability of data, point (c) in section “[Documenting Is \(Part of\) Designing](#),” when higher factors should be used).

Added materials' strengths in these cases may be reduced with appropriately lower safety factors.

- The case of point (d.1) (ii) above is also valid:

(d.3) Strength of materials in large critical volumes may be used with their **mean** values. Moreover, independent of the volume of critical regions, whenever in a resistance model a factored strength may result in higher resistance values, the corresponding " γ_M " should be taken equal to unity. This is, for instance, the case with the calculation of the mechanical volumetric ratio " ω_w " of confining materials, in which concrete strength appears in the denominator and, if factored, results in a fictitious increase of " ω_w " (by 30 % or 50 %) that is against safety.

(e) Model uncertainty factors.

Design of structural interventions against seismic actions needs to use model uncertainty factors much more frequently than in any other structural engineering field, for various reasons, including:

- In case of previous structural damages, a rather unknown degree of redistribution of action effects has taken place; hence the occasional need for γ_{Ed} values to increase calculated action effects.
- The number of variables entering the models of redesign is larger than in any other case, resulting in higher uncertainty. Besides, force transfer mechanisms along interfaces between "added-to-new" materials show disproportionately higher scattering. It is therefore customary to use γ_{Rd} values to reduce calculated resistance values.
- Feedback information to validate the redesign models used is commonly insufficient. Consequently, relatively higher γ_{Rd} values are used.

It is noted that γ_{Rd} values used in calculating capacity design quantities do not entirely belong to this category of factors.

Better Do "Something than Nothing" (Selection of Redesign Targets)

- (a) The social interest for the seismic safety of existing buildings is better served if the following principle is applied: instead of maximalistic targets of structural intervention, necessitating unavailable funds and very long time of execution, it is better to select a less ambitious redesign target, easier to be implemented (in terms of both investment and social costs).

In fact, the relatively high burden put on the present generation which should supposedly undertake the full strengthening of existing structures in favor of future generations hinders in many cases the implementation of any strengthening. Thus, the risk of social losses due to future earthquakes remains high for rather long periods, even in relatively wealthy seismic regions. That is why it is reasonable to encourage owners to proceed to any economically "feasible" intervention whenever this is possible for them and the local community – instead of the ambition to apply on an existing structure the seismic design rules required for new structures.

- (b) In doing so, however, it is advisable to follow as much as possible a more systematic scheme of redesign target selection, as it is roughly described below.

For the redesigned structure, a lower future performance level may be adopted (see Table 1), provided that this is compatible with the social function of the structure.

On the other hand, as it was discussed in point (a) of section "[Modified Reliability Level](#)," it is reasonable to select a much higher acceptable probability of exceedance P_f of seismic action than those used in designing new structures. If, for instance, a P_f value as high as 50 % is chosen (in a time reference of 50 years for buildings), the seismic ground acceleration for redesign may be reduced approx. by 40 % of the value applicable to a 10 % probability of exceedance.

The combination of a redesign performance level and of an acceptable probability

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions, Table 1 Redesign performance levels

	A	B	C
Future performance	Uninterrupted function	Life and property protection	Non-collapse
Acceptable damage	Insignificant	Repairable local plastic hinges	Beyond repair

of exceedance constitutes a “**redesign target**.” Lower levels of such targets are easier to be implemented, provided that they contribute to the gradual increase of seismic safety of the existing building stock:

- (c) By definition, an existing structure has consumed part of its **life period expectancy** L_t . Consequently, the duration of its remaining life is reduced, and (for a given probability of exceedance P_f) the value of the seismic action to be used in the redesign of the structural intervention could be reduced, in accordance with the following well-known equations:

$$\begin{aligned} \text{Mean recurring period } T_m &= L_t : [-\ln(1 - P_f)] \\ \text{Ground acceleration } a_g &= \exp(k_1 \log T_m + k_2) \end{aligned} \quad (3)$$

where k_1 , and k_2 are appropriate site-specific constants.

Nevertheless, shorter remaining life periods can rarely be reliably taken into account for the following reasons:

- Conventional L_t values (e.g., 50 years for buildings) are not confirmed in practice; normally, buildings are much longer used, while the “technical” life of bridges may be shorter than anticipated.
- Environmental influences may significantly modify lifetime periods, producing additional uncertainty in any numerical consideration of this issue.

Conceptual Redesign

- (a) Prior to any decision about the kind and the extent of a structural intervention in an

existing building, some basic qualitative rules of conceptual nature should first be considered. Happily enough, these rules are very similar to those applied in the conceptual design of new buildings. A brief list of such basic rules follows below (see also Fardis 2009, Ch. 2). Qualitative decisions and subsequent quantitative redesign of structural interventions regarding seismic upgrading should consider the possibility to **improve** the following characteristics of the building:

- Clarity of the lateral load resisting system, including its simplicity and uniformity
- Contribution to the symmetry and the regularity in plan
- Possible increase of torsional stiffness about a vertical axis
- Possible regularity in elevation of mass and lateral stiffness distribution
- Adequate redundancy
- Reestablishment of the continuity of vertical and lateral force paths, without stress or deformation concentrations
- Contribution to the effectiveness of floor diaphragms at all levels
- Possible reduction of total mass
- Avoidance of possible adverse effects of infills

- (b) Similarly, the first step of any structural intervention should be the evaluation and upgrading of the possible **environmental** influences that directly reduce both the available strength and ductility of materials. As an example, it is reminded here that corrosion of steel bars reduces the available diameter of a bar, it may produce longitudinal cracking to concrete reducing the sufficiency of anchorages (i.e., threatening the possibility of the bar to reach its yielding stress), and finally it may reduce the ductility capacity of steel

itself. Consequently, **maintenance** seems to be the first step of any seismic upgrading (see, e.g., Schiessl 1992).

Selection of Intervention Strategies

Two categories of such strategies are encountered in the practice of structural intervention. Optimal solutions are sought in both cases.

“Spread-Soft” or “Local-Strong” Intervention?

- (a) Critical regions of a rather large number of building elements are repaired and/or strengthened: this apparently soft method, however, increases disproportionately the social costs of the intervention; tenants should normally be relocated to other buildings, whereas previous professional activities in the building under structural interventions are canceled.
- (b) Instead, additional (external or inserted) walls made of RC or appropriate steel bracings are connected with the existing vulnerable frame in few selected bays and appropriately founded. This alternative intervention reduces considerably the disturbance of the inhabitants but necessitates additional design and construction efforts – especially in connection with problems related to the rotation (or rocking) of the foundation of such new walls.

Additional Resistance (Strength and Stiffness) or Additional Ductility?

Theoretically, for a given performance level, it is possible to satisfy safety requirements by means of upgrading (i) resistance (i.e., strength and stiffness) and/or (ii) ductility. In the first case, in terms of a “pushover” analysis, seismic demand is also increased, whereas the critical displacement (ending the capacity curve) is reduced (see point u_1 in Fig. 6). In the second case, seismic demand is reduced, and the critical capacity displacement is increased (point u_2 in Fig. 6). These two equivalent results however may significantly differ in terms of costs; ductility upgrading may occasionally be more expensive. An **optimum solution** should be sought.

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions, Fig. 6 In a pseudo-acceleration vs. pseudo-displacement plot, two intervention strategies are depicted, against a given seismic elastic spectrum: (a) upgrading of resistance (u_1) and (b) upgrading of ductility of the system (u_2). Optimization is sought

In-Elevation Uniformity of Safety Margins

Any structural intervention should contribute as much as possible toward a uniform distribution of the final margins of safety (in terms of resistance against lateral loading) along the height of buildings – provided however that a correct provision of seismic action effects (ΣE_i) on each floor is available and a realistic calculation of the resistances of building elements (ΣR_i) is possible. A quasi-uniform distribution of the safety margin ($\Sigma E_i - \Sigma R_i$) offers the possibility that all floors yield almost simultaneously. The latter ensures uniform dissipation of seismic energy along the entire height of the structure. Thus, the formation of “soft” stories is avoided, and the ductility demand at each floor is reduced.

A typical deviation from this principle is related with the ground floor of some multistory buildings in Southern Europe and Southern America: brickwork infills are frequently missing in ground floors (thus creating a soft floor); besides, a strong strengthening of the building elements of this floor relocates “softness” to the above floors, i.e., induces increased probability for this floor to suffer from locally concentrated damage (Fig. 7).

Retrofitting and Strengthening of Structures: Basic Principles of Structural Interventions, Fig. 7 (a) Initial soft ground floor ("pilotis"): seismic damage will be

concentrated there. (b) Overstrengthened ground floor relocates "softness" to the above floors

"Designer and Constructor"

In the field of repair and strengthening of structures, a plethora of alternative innovative materials and new construction methods exist. Therefore, it would be inconceivable for a designer to ignore them. Consequently, in this field (more than in designing new structures), the usual dichotomy **designer/constructor** should be blunted. For example, developments in the use of flat jacks to facilitate (and quantitatively check) propping of building elements under intervention should be well known to any designer.

Besides, **interdisciplinarity** in this field is more desirable. For instance, a structural engineer may commit a considerable mistake if they neglect the soil nonlinearity, due to which the rotation center of the foundation of an added wall may lay in a quite eccentric position (see section "[Introductory Example](#)").

Aseismic Upgrading of Monuments

(a) Introduction

- An inadequate structural intervention in a monument violates the value of human life and the survival of the monument.
- An excessive structural intervention violates a series of "monumental values," such as:
 - Aesthetic form
 - Historicity

Further, such an excessive structural intervention may violate the desirable reversibility of restoration measures.

- "Social values" may also be at risk, including the need for economy and for possible new uses of the monument under consideration.
- An optimization should be sought, with the difficulty that these antithetic values are of different nature, and they may not be amenable to a common unit (i.e., money).

(b) Selection of redesign seismic action

In view of this complex situation of "values at risk," it would be wrong to use seismic actions prescribed by codes of practice for the design of new buildings or bridges in seismic redesigning of monuments. Theoretically (for a given conventional reference time), a new probability of exceedance should be sought, taking into account that any additional upgrading of safety would entail "costs" in terms of:

- Money
- Modification of aesthetic form
- Devaluation of historicity
- Reduction of reversibility
- Possible difficulties in new uses

It is expected that such an original increase of "costs" would occasionally result in a considerable increase of the acceptable probability of exceedance of the value of seismic actions that will be used in the redesign of the resistance of a monument.

In more practical terms, however, an interdisciplinary group of experts offers justified

opinions on two or three alternative solutions based on lower and relatively higher seismic loads, depending, i.e., on their consequences on the aforementioned monumental values (see Tassios 2011).

The Retrofitting “Construction Principle”

- (a) The originality and the subtlety of structural interventions are recognized.

In the case of added **structural materials**, the following difficulties are usually encountered, inter alia:

- Precision regarding the forces induced by propping
- Cleanness of interfaces
- Geometrical precision in added thin layers
- Sensitivity of operations such as gluing, welding and the like
- Originality of methods like grouting and injections
- Health protection of personnel working in damaged buildings or handling chemicals in several cases

In the case of installation of dampers, base isolators or active protection devices, construction operations become closer to mechanical engineering.

- (b) Because of these rather delicate conditions, structural upgrading construction-stages need additional and better organised Inspection. Safety is a multidimensional vector with several components; and it may be jeopardised by a deficient Inspection, especially in the case of structural intervention.

Consequently, good seismic upgrading-design files should be accompanied by an appropriately detailed set of technical Specifications and with explicit suggestions for additional Inspection wherever needed.

Summary

This article reviewed the basic principles of structural interventions for the seismic

assessment, repair, and strengthening of existing structures. After a brief historical background, the need for such principles is first described and subsequently several basic views toward a rational foundation of assessment and redesign are presented.

To this end, a basic motto “First understand, then withstand” is established underlining the importance of complete documentation, systematic knowledge of pathological mechanisms, long experience on available traditional and modern methods of retrofitting, as well as familiarity with the use of advanced redesign models. The significance of the displacements along the interface between existing and added materials, as well as the principle of the differential loadings of these two categories of materials, has been subsequently explained.

The problem of the target reliability level in redesigning structural interventions is then discussed in detail, together with the modified values of safety factors. Further, the selection of “redesign targets” (possibly new performance levels and new probabilities of exceedance of the seismic action) is discussed, together with possibly modified remaining life periods of the existing structure.

Finally, alternative intervention strategies are presented, together with the principle of the final uniformity of safety margins in the elevation of the retrofitted building. The entry closes with some considerations regarding the execution of a structural intervention and the role of the designer in this respect.

Critique on seismic hazard analysis; Limitations on seismic hazard analysis; Preference of DSHA over PSHA; Problems with probabilistic seismic hazard analysis

Introduction

In earthquake-prone regions of the world, it is a common practice to assess anticipated hazard severity for land-use planning, emergency management, and structural design load considerations for public safety applications. Generally, strong ground motion hazards would impact a large area, and displacement hazards could affect a relatively small area localized along the fault trace of surface-faulting earthquakes. This section will *review* inputs for obtaining a generic ground motion as the most pervasive earthquake hazard and that without site-specific considerations. Note that soft soil sites are generally more hazardous than stiff soil or rock sites, and such site-specific conditions should be characterized realistically in practice for ground response analysis.

Implications of the inputs for seismic hazard assessed results will be discussed. The hazard

assessment is accomplished by performing seismic hazard analysis (SHA) procedures using either a deterministic or a probabilistic approach (Reiter 1990). The deterministic results provide hazards anticipated from the *largest* potential events and the probabilistic from prescribed *recurrent* event(s). The ground motion hazard is obtained from the mean or a certain level above the mean as applied to the ground motion prediction equations (GMPEs) in both the deterministic and probabilistic approaches according to policy or guidelines.

Background

SHA and its results have been well known and used, but the inputs are not well understood by the public, users, and even some analysts, especially those using PSHA software. Analysts and users should understand first the inputs, the approaches, and the limitations in the results before the intended applications.

The deterministic seismic hazard analysis (DSHA) and its enhanced neo-DSHA (NDSHA) define hazards anticipated from a single magnitude of the *largest* potential earthquake or maximum credible earthquake (MCE) scenario centered on each of the considered seismogenic faults (e.g., Mualchin and Jones 1992; Panza et al. 2012), independent of the earthquake recurrence times or the ground motion return periods. The justification is that (1) such a single *largest* earthquake encompasses and thus automatically considers impacts from all other possible smaller events, (2) earthquakes can occur at any time regardless of its short or long recurrence estimated times or low or high estimated slip rates of the faults, and (3) ground motion for MCE would exceed any physically realistic ground motion return periods. In addition, NDSHA provides at each site a set of synthetic seismograms generated for all the earthquake scenarios. The usual criticisms on DSHA are its lack of magnitude recurrence times or ground motion return periods and lack of quantifying uncertainty in the results, but these are truly more of misunderstanding in the practice of DSHA.

The probabilistic seismic hazard analysis (PSHA) determines hazards anticipated from a number of earthquakes on each of the same seismogenic sources as used in DSHA whose magnitudes, however, are defined according to their recurrence times (e.g., Cornell 1968). The justification is that (1) hazards from more or less active faults are “equitably” accounted for through the recurrences or its equivalents, (2) integrating or combining impacts from all significant magnitudes and not just one single MCE event is comprehensive, and (3) uncertainty has been accounted for in each step of the analysis, in the GMPEs, and in the final results. The usual criticism is its lack of transparency in the results with respect to the inputs (due to an elaborate analysis with emphasis on uncertainty) which has created enormous problems. Revealed problems on several aspects and results of PSHA that remain unresolved (e.g., Klügel 2005, 2007; Kossobokov and Nekrasova 2012; Nekrasova et al. 2013; Wang 2011; Wang and Cobb 2012; Wyss et al. 2012) began to accumulate and put the future of the probabilistic approach uncertain.

In general, DSHA/NDSHA provides more conservative ground motion values when compared with PSHA’s short to moderate ground motion return periods. However, PSHA can produce extremely large ground motion values for very long return periods, much greater than would be produced by MCE magnitude events. Such PSHA’s extreme ground motions are controversial and physically not supportable even though it can be easily calculated theoretically. Both DSHA and PSHA approaches have advantages and disadvantages as well as pros and cons, but a detailed discussion is outside the scope of this section.

For a coherent framework, DSHA and PSHA inputs will be simplified into two, namely, (1) earthquake magnitudes and (2) strong ground motion attenuation relationships, or GMPEs appropriate for the region. These two will be understood as *derived* inputs because they are obtained from analysis and interpretation of (a) seismologic and geologic *data* of instrumentally recorded, historic, and paleo-earthquakes; (b) strong ground motion recorded *data*; and (c) earthquake source or fault *data*. These data,

subjected to analysis and interpretation, are the *fundamental* inputs. Note that GMPEs are not required in NDSHA (e.g., Panza et al. 2013) which has an advantage over PSHA.

Moment magnitude scale (Hanks and Kanamori 1979) is used in modern practice to avoid saturation of large-magnitude earthquakes in the Richter scale. The moment magnitude scale takes advantage of the seismic moment derived for an equivalent double-couple earthquake source and which measures the strength (i.e., magnitude) of an earthquake without any saturation (Aki and Richards 2002). Hereafter, magnitude means moment magnitude.

Inputs for Seismic Hazard Analysis

Magnitude for DSHA

Only MCE magnitude for each of the considered seismogenic faults is derived as the required input. The magnitude is generally estimated from basic inputs of the length and area of fault by applying it to the empirical relationships between fault lengths or areas and magnitudes established from observations (Wyss 1979; Bonilla et al. 1984; Wells and Coppersmith 1994). The relationships are also established according to the style of dominant fault displacements, namely, strike-slip, normal, and reverse/thrust faults. Fault displacement can also be used for magnitude estimates but such data may not be readily available for all the faults.

Fault length is obtained by measuring it, usually from geologic maps based on field investigations. The width of the fault is estimated from the dip and depth of the fault, noting that fault width (W) is given by:

$$W = h / \cos(\delta),$$

where h is the depth of the fault and δ is the angle of the dip.

The dip can be obtained from geologic mapping or focal mechanism of earthquakes on the fault system. The focal depth distribution of earthquakes in the area can provide the dip and depth of the fault. Fault area is calculated from

fault length and width. Though actual fault surface would be quite complex, this representation is an approximation as a plane.

The length, width, and area of a causative fault can be approximated from the aftershock distribution zone of earthquake, preferably in conjunction with a fault map. This seismological method is possible only *after* the occurrence of an earthquake and provides data for developing empirical relationships between observed fault parameters and magnitudes.

By applying fault length or area to the appropriate empirical relationships, magnitude is obtained in a straightforward manner. Typical examples from Wells and Coppersmith (1994), without the standard deviations of the regression equations, are:

$$M = a + b * \log_{10}(\text{SRL}),$$

where SRL is the surface fault rupture length (km) and $a, b = 5.16, 1.12$ for strike-slip fault; $5.00, 1.22$ for reverse fault; $4.86, 1.32$ for normal fault; and $5.08, 1.16$ for all faults.

$$M = a + b * \log_{10}(\text{RA}),$$

where RA is the fault rupture area (sq-km) and $a, b = 3.98, 1.02$ for strike-slip fault; $4.33, 0.90$ for reverse fault; $3.93, 1.02$ for normal fault; and $4.07, 0.98$ for all faults.

For example, for a strike-slip fault, a change in fault length by twice or half will change the magnitude by about 0.3 magnitude unit, and an increase or decrease in fault length by 10 or 20 km by about 0.1 magnitude unit. For well-mapped faults, errors in lengths by 10–20 km are most unlikely and would be much less, and the uncertainty in MCE magnitude estimate would be negligible for all practical purposes. Therefore, uncertainty in MCE magnitude is not an issue in DSHA. An enhanced exploitation of geologic information is allowed by NDSHA (Panza et al. 2013).

Magnitudes for PSHA

PSHA used a range of magnitudes, from a minimum value, typically around magnitude

4, to the maximum or upper bound magnitudes for faults or areal sources. The upper bounds are comparable to MCE magnitudes. Considerable efforts have been made to estimate the upper bound magnitudes by using logic-tree analysis to quantify the uncertainty. However, such analysis has not demonstrated better estimates of MCE magnitudes. The weights or inputs at every step in the logic-tree analysis are not real data but experts' opinions with undefined uncertainty.

Again, magnitudes for seismogenic faults and areal zones are defined according to their *recurrence times* in the frequency magnitude relationships based on historic or paleo-seismic (magnitudes and occurrence times) regional data. A homogeneous earthquake catalog with “completeness” of earthquakes is the prerequisite for PSHA but not usually achieved. From such data, the most common frequency magnitude relationship or the “Gutenberg-Richter” equation for the source region has been derived, as proposed by Richter (1958):

$$\log_{10}N = a - bM,$$

where N is number of earthquakes of magnitude M or greater per year and a and b are constants usually estimated with regression analysis.

The recurrence time (in years) is the reciprocal of N, or $1/N$. Even though there are variations, the general form of this long-established equation has been the rule over the years. Availability of reliable earthquake data is required and applicability of the equation to specific faults is an open question that remains unresolved.

It should be noted that there is no formal time-series analysis operated on magnitudes and origin times to obtain recurrence times. Magnitudes in the observed time period are lumped together for calculating N arithmetically. There are no criteria for the spatial extent and data availability for developing the equation. Implications of these points are that recurrent magnitudes may not be as assumed and have undefined uncertainty.

Recurrence can also be obtained from slip rates on a seismogenic fault from paleo-seismic “displacement” data (Wallace 1970; McCalpin 1996).

Slip rate is derived from the total slip (i.e., displacement) along a fault over a long period of time even though the slip (centimeters to meters) during an earthquake takes only seconds. Mean recurrence interval (RI) is calculated from the equation:

$$RI = D/(S - C),$$

where D is displacement during a single earthquake, S is coseismic slip rate, and C is creep slip rate which is assumed zero for most faults. RI is equivalent to $1/N$, where N is given in the Gutenberg-Richter equation.

Note that displacements on a fault surface during an earthquake are truly multivalued and the meaning of D is not yet defined. Therefore, the value of slip rates has undefined uncertainty.

In principle, displacement can be correlated to magnitude by using empirical relationships between magnitude and displacement (Wells and Coppersmith 1994) given by:

$$M = a + b * \log_{10}(MD),$$

where MD is maximum displacement (m) and a , $b = 6.81, 0.78$ for strike-slip fault; $6.52, 0.44$ for reverse fault; $6.61, 0.71$ for normal fault; and $6.69, 0.74$ for all faults.

$$M = a + b * \log_{10}(AD),$$

where AD is average displacement (m) and a , $b = 7.04, 0.89$ for strike-slip fault; $6.64, 0.13$ for reverse fault; $6.78, 0.65$ for normal fault; and $6.93, 0.82$ for all faults.

In general, displacement or slip on many faults is not readily available, and therefore, slip rate may not be applicable in a large majority of seismogenic faults. Note that the significance of a specific displacement observed on a fault is undefined in characterizing the associated earthquake.

Ground Motion Prediction Equations (GMPEs) for DSHA and PSHA

The most commonly used ground motion parameter in SHA is peak ground acceleration (PGA) even though it is not well correlated with induced

structural damage by earthquakes. Nevertheless, it is used as a scaling factor for developing seismic design load spectra and simulating synthetic seismograms. Obviously, structural damage is best correlated with intensity such as Modified Mercalli which has been neglected in favor of using quantitative instrumental recordings. Reexamination of intensity scale is in order for complementing or supplementing current practices because of difficulty in interpreting instrumental records for structural damage and performance.

GMPEs show PGA as a function of “distance” from earthquake source for various magnitudes, starting with high PGAs near the source and gradually decreasing with increasing distances from the source (e.g., Schnabel and Seed 1973; Sadigh et al. 1997; Joyner and Boore 1981; Campbell 1981). Common distances used are epicentral distance, nearest distance to fault surface, and nearest distance to surface projection of fault. For proper comparisons of various GMPEs, the adopted distances should be related correctly.

The so-called Next Generation Attenuation (NGA) GMPEs have generated a new series of publications (Abrahamson and Silva 2008; Boore and Atkinson 2008; Campbell and Bozorgnia 2008; Chiou and Youngs 2008; Idriss 2008). The main idea of NGA was to have a uniform data for GMPE researchers so that they produce better or comparable results. It remains to be seen if the expectation is true. It should be noted that uniform data preparation is not necessarily a neutral activity and serious bias can occur in the process for various reasons, including intention to influence on the results for “special interest” applications. Moreover, independence of researchers is most valuable and working under such a condition may not produce best objective results.

In general, variations from the general trend of attenuation curves or GMPEs are, to a first approximation, due to variabilities in (1) subsurface physical configurations and conditions along the wave propagating path from source to site and (2) preferential focusing of seismic energy in the direction of fault rupture propagation.

The (aleatory) variability and (epistemic) uncertainty quantified as the standard deviation

“sigma” of $\log_{10}$ (PGA) in the GMPEs have remained stable within 0.15 and 0.35 over the last 40 years (Stasser et al. 2009). In other words, GMPEs have been developed as best as can be in spite of certain defects. GMPEs have been used in confidence over the years with prudent professional judgments.

Ground Motion Prediction for NDSHA

NDSHA produces realistic time series describing possible ground motions and does not require appealing to any variant of GMPEs. In the coming years, the reliability of NDSHA will be tested by real events to become more and more mature.

Basic Inputs for DSHA and PSHA

These are listed without discussion:

Historic seismicity from earthquake catalog, including completeness and homogeneity
Strong motion recorded raw and analyzed data and interpreted results
Paleo-seismicity from investigations and interpretation
Detailed fault information: location, geologic age, three-dimensional geometry including continuity or segmentation, style of movement, associated site and regional seismicity, assumed extent of rupture
Information about the structural model for the studied area (for NDSHA)

Implications of Inputs on Hazard Results

SHA results will be as good as the inputs. Accurate inputs will produce reliable results. Questionable inputs will produce doubtful results. Implications on the quality of results for DSHA/NDSHA and PSHA when the same inputs are used will be discussed. The nature of inputs and the implied hazard results will be examined for DSHA/NDSHA and PSHA.

Magnitudes

1. For DSHA/NDSHA, MCE magnitudes are based on fault input that are based on mapping and earthquake analysis. Fault lengths

are well established and its width and area are reliably derived. The nature of the empirical relationships is such that the MCE magnitude estimates are robust given the unlikely and conservative uncertainty in fault length. With such inputs, DSHA/NDSHA results are stable and expected to be reliable.

2. For PSHA, recurrent magnitudes will vary according to the quality and quantity of historic and paleo-seismic earthquake data. Regions with well-recorded history such as in Europe and China are expected to have better recurrent magnitudes. Well-studied faults such as the San Andreas Fault in California are expected to provide recurrent magnitudes for the largest events but not necessarily for the lower magnitudes. Faults with inadequate or no earthquake data will not have reliable recurrent magnitudes. Because in real earthquakes, slips are multivalued, and therefore, slip rates based on specific slip measurements have undefined uncertainty. The recurrence equation itself has no formal time-series analysis but just lumped together seismicity data within the observed time periods and therefore contains undefined uncertainty. Translating frequency magnitude relationships of a region to specific fault (s) has undefined uncertainty. A recent research reported that the concept of recurrence time itself can be misleading or even meaningless and the quantitative determination of such time remains only a dream (Bizzari and Crupi 2013).

Based on the above points and several involved undefined uncertainties, recurrent magnitudes are not reliable and so are the PSHA results.

Ground Motion Prediction

3. Both DSHA and PSHA used GMPEs. The stable nature of GMPEs over the last 40 years as noted above demonstrated the maturity and reliability of GMPE. Improvement may be expected from better understanding of earthquake source physics and unlikely from more statistical analysis such as

separating into aleatory variability and epistemic uncertainty. GMPEs as the derived inputs for DSHA and PSHA are stable and well established. GMPEs have been used in confidence over the years with prudent professional judgments.

4. The obvious limitations of GMPEs are due to neglecting (a) variation in subsurface conditions along the wave propagating path from source to site, (b) site-specific effects, and (c) preferential focusing of seismic energy in the direction of fault rupture propagation.
5. NDSHA computes realistic time series of possible ground motions without any variant of GMPEs. This is a distinct advantage to be tested by real events in the coming years and become mature for wide applications.

Using Same Inputs by DSHA/NDSHA and PSHA

6. For given faults and a given GMPE, the quality of results for DSHA/NDSHA depends on the accuracy of estimated MCE magnitude based on fault parameters and (a) GMPE for DSHA or (b) the computation for NDSHA. However, the quality of results for PSHA depends on additional parameters: earthquake recurrence based on seismicity or slip rate data; recurrence has undefined uncertainty.

Because of more inputs required by PSHA, which are associated with undefined uncertainty, the quality of the results will not be as good and transparent as that for DSHA/NDSHA. It will be difficult to evaluate the quality of results in PSHA as it does not produce transparent results like DSHA/NDSHA.

Comments on Inputs for DSHA/NDSHA and PSHA

7. DSHA/NDSHA requires fault geometry and geographic location of faults which can be readily obtained from tectonic maps and earthquake locations from seismicity maps. In a nutshell, input MCEs for sources are estimated as stated above and ground motion hazards can be obtained by using input GMPE in DSHA and by direct computation in NDSHA.

8. PSHA requires comprehensive homogeneous earthquake catalog and displacement data of faults. Earthquake catalogs for many areas are not always comprehensive, homogeneous, or complete. Recurrence equations have to be derived from such data but the applicability of such equations on individual faults remains problematic. Fault displacements provide paleo-earthquakes to extend earthquake history and can provide slip rate for deriving recurrence intervals. However, displacements are available only for a few faults. Moreover, the significance of specific displacements is undefined, being just one of the multivalued displacements during an earthquake centered on a fault. Furthermore, recurrence times are not based on time-series analysis and thus have undefined uncertainty. The concept of recurrence may be even meaningless and the quantitative determination remains only a dream.
9. PSHA inputs are more difficult and involved with several undefined uncertainties. PSHA's distinctiveness is to incorporate differences in seismic activity of faults. Unfortunately, this has not been achieved so far in a realistic manner.
10. In contrast, DSHA/NDSHA inputs are easier to obtain, and the results are stable and therefore expected to be reliable. Obviously, the implication is that DSHA/NDSHA seems more reliable and much more economic than PSHA.

Summary

The inputs for DSHA/NDSHA are simple, limited, and easy to obtain. The hazard results are stable and expected to be reliable. The absence of recurrence is an advantage because short or long recurrent earthquakes can occur at any time. NDSHA is advantageous without the need to use GMPEs. The procedures for DSHA should be more formalized as in PSHA. The simplicity and strength of DSHA should not be confused with the complexity and sophistication of PSHA.

The inputs for PSHA are not easily obtained and quite involved. Derived quantities such as

recurrence and slip rate are associated with undefined uncertainties. Therefore, the results are expected to be doubtful. A simpler PSHA procedure than the currently advanced may be more realistic.

The concept of recurrence as the foundation for PSHA can be misleading or even meaningless and the quantitative determination of such recurrence time remains unrealistic, and the value of such results questionable. In contrast, the concept of MCE and its magnitude determination are well established.

PSHA is much more expensive due to data requirements and complex analysis. There is a diminishing return in spending more money for PSHA. In contrast, DSHA is economic and the results are stable and expected to be reliable.

Introduction

Design can be regarded as an action with decision making for finding an acceptable outcome

satisfying (usually optimally) a set of specified requirements called design constraints. In general, the design model (design object), the objective function, and the design constraints include various uncertainties. For example, mechanical properties of structural members have variability due to initial manufacturing errors, material deterioration, and temperature dependence (see Fig. 1). Young's moduli and strengths of concrete exhibiting large variability and strengths of steel indicate not a small uncertainty. In addition, it is well known that passive dampers used in structural control and base-isolation systems have a large degree of variability compared to ordinary structural members. This characteristic is reflected in the structural design of passive-controlled structures and base-isolated structures in Japan. From another viewpoint, it is often pointed out that there remains a large uncertainty in the modeling and analysis of structural systems, e.g., shear strengths of reinforced concrete members, reinforced concrete shear walls, steel plate shear walls, steel braces, and super high-rise buildings (Minami et al. 2013). Some of these phenomena possess inherent uncertainties which may not be possible to overcome by the enhancement and upgrade of modeling.

Regarding the disturbances for design objects, design input ground motions have a larger variability compared to the structural member variability. This may result from the insufficient research in the modeling of ground motions together with physical unclearness of ground media (Takewaki et al. 1991, 2011, 2012, 2013; Conte et al. 1992; Takewaki 2006, 2008, 2013; Ariga et al. 2006; Celebi et al. 2012).

Based on these observations, it is recognized well that the reliable design of building structures with greater robustness and reliability can be achieved by taking into account the input disturbance uncertainties and structural parameter uncertainties. In order to get a reliable design with greater robustness, the introduction and definition of robustness are essential. An example measure of the robustness is explained here and its application to the robust control of building structures with uncertain input disturbance and structural parameters is presented. Since

Robust Control of Building Structures Under Uncertain Conditions,

Fig. 1 Variation of structural response under uncertain structural parameters in a passively controlled building

a method for quantifying the response variability due to input disturbance and structural parameter uncertainties is needed in the robust control of such building structures, an enhanced and efficient methodology is explained for evaluating the robustness of an uncertain building structure with passive dampers and an uncertain base-isolated building structure.

A number of studies on uncertainty analysis have been accumulated so far. Most studies are aimed at investigating the upper bound of the structural responses considering the uncertainties of structural parameters (e.g., see Ben-Haim and Elishakoff 1990; Ben-Haim 2001, 2006; Takewaki and Ben-Haim 2005; Takewaki 2006, 2013; Takewaki et al. 2012; Kanno and Takewaki 2006; Elishakoff and Ohsaki 2010). It is well understood and accepted that the interval analysis is a representative of the reliable uncertainty analysis methods. It seems that the concept of interval analysis was introduced by Moore (1966). Alefeld and Herzberger (1983) have then conducted the pioneering work. They treated

linear interval equations, nonlinear interval equations, and interval eigenvalue analysis by using interval arithmetic. Since their innovative achievements, various interesting interval analysis techniques based on the interval arithmetic algorithm have been proposed by many researchers (e.g., Dong and Shah 1987; Koyluoglu and Elishakoff 1998; Mullen and Muhanna 1999; Qiu 2003).

More recently, some sophisticated interval analyses using Taylor series expansion have been proposed by Chen et al. (2003, 2009), Chen and Wu (2004), and Fujita and Takewaki (2011a, b, 2012a, b). In the early stage of the interval analysis using Taylor series expansion, the first-order Taylor series expansion was introduced and investigated for the basic problems of static response and eigenvalue. Chen et al. (2009) developed a matrix perturbation method using the second-order Taylor series expansion and obtained an approximation of the bounds of the objective function without interval arithmetic. They pointed out that the computational load can be reduced

from the number of calculation 2^N (N : number of interval parameters) to $2N$ by neglecting the non-diagonal elements of the Hessian matrix of the objective function with respect to interval parameters. Furthermore, Fujita and Takewaki (2011a) have proposed the so-called updated reference-point (URP) method. In this method, the critical uncertain structural parameters can be obtained by the approximation of second-order Taylor series expansion, and the upper bound of the structural responses can be evaluated by reanalyzing the structural response using critical uncertain structural parameters. Their method has been extended to nonlinear inelastic problems (Fujita and Takewaki 2012a).

In the structural design procedure, the robustness of building structures should be taken into account and incorporated under various uncertainties of structural parameters and inputs (e.g., see Takewaki et al. 2012). Ben-Haim (2001) has proposed an index, called the robustness function, for measuring the degree of the robustness based on the info-gap decision theory. The concept of the info-gap models and the robustness functions will be explained in the following section. In the info-gap model, the uncertainty of structural parameters is assumed to be given by a non-probabilistic model, e.g., an interval model used in the interval analysis. According to the definition of the robustness function, it can be regarded as a quantitative index of the robustness of the building structure (Takewaki and Ben-Haim 2008).

Here an efficient evaluation method using the robustness function with respect to the constraint on seismic performance is presented and explained by taking advantage of the sophisticated uncertainty analysis method called the URP method. A planar shear building model with passive viscous dampers is used for the robustness analysis (see Fig. 1). By comparing the robustness functions for various damper distributions, a preferable damper distribution is investigated to enhance the robustness of the building model under various uncertainties of structural parameters.

An application to base-isolated buildings with hysteretic responses is also explained.

Robustness Function for Seismic Performance

In the structural design of buildings in earthquake-prone countries, the constraints on dynamic responses for earthquake loadings are major concerns and should be taken into account in an appropriate manner. In these design constraints, the dynamic responses such as maximum horizontal displacement and member stress evaluated by a reliable time-history response analysis are required especially in important structures to check the satisfaction of the performance criteria. The necessity of using the time-history response analysis depends on the seismic-resistant design codes of the countries. Even if all the design constraints are satisfied at the initial construction stage, some responses to external loadings during service life may violate such constraints due to various factors resulting from randomness, material deterioration, temperature dependence, etc. To overcome and remedy such difficulty, the introduction of the robustness function which represents the degree of robustness of the objective building structure may be one of the effective solutions for the design of more robust building structures under uncertainties (Takewaki et al. 2012).

In this section, a definition of the robustness of building structures for the seismic performance is introduced based on the info-gap model (Ben-Haim 2001). According to the info-gap model, the uncertainty of structural parameters is defined as a non-probabilistic model.

As for convex models, several useful methods can be used (Ben-Haim and Elishakoff 1990; Ben-Haim et al. 1996; Pantelides and Tzan 1996; Tzan and Pantelides 1996; Baratta et al. 1998). A convex model is defined mathematically as a set of functions. Each function is a realization of an uncertain event. Convex models for ground motion modeling depend on the level of prior information available. Examples are a local energy-bound convex model, an integral energy-bound convex model, an envelope-bound convex model, a Fourier-envelope convex model, and a response-spectrum-envelope convex model (Ben-Haim et al. 1996). One of the merits of the convex

models is the capability of prediction of the maximum or extreme response of structures to unknown inputs. The details of convex models can be found in appropriate references (Ben-Haim and Elishakoff 1990; Ben-Haim et al. 1996).

In the following, uncertain structural parameters are assumed to be described by an interval model. The interval parameter $\mathbf{X}^I$ is defined by

$$\mathbf{X}^I = \{X_i^I | [X_i^c - \Delta X_i, X_i^c + \Delta X_i], i = 1, \dots, N\} \quad (1)$$

In Eq. 1, $()^I$ and $[a, b]$ represent the definition of an interval parameter where a and b are the lower and upper bounds of the interval parameter, respectively. Furthermore, $()^c$, $\Delta()$ and N denote the nominal value of an interval parameter, half the varied range of the interval parameter, and the number of interval parameters, respectively. When the uncertainty of structural parameters is described by the interval vector, it means that the feasible domain of interval parameters is constrained into an N -dimensional rectangle.

In the info-gap model (Ben-Haim 2001), the level (or degree) of uncertainty is defined by a single uncertain parameter α . Based on the definition of an uncertain parameter α in the info-gap model, the feasible domain of the interval parameter $\mathbf{X}^I$ can be represented by an uncertainty set $\mathbf{X}^I(\alpha) \in \mathbf{R}$ which is described by

$$\mathbf{X}^I(\alpha) = \{X_i^I | [X_i^c - \alpha \Delta X_i, X_i^c + \alpha \Delta X_i], i = 1, \dots, N\} \quad (2)$$

In Eq. 2, ΔX_i is a prescribed value of half the varied range of the interval parameters. It should be noted that the level (or degree) of uncertainty can be described by the combination of ΔX_i and α . Therefore, it can be mentioned that the uncertainty level of the uncertainty set $\mathbf{X}^I(\alpha)$ varies according to the variation of uncertain parameter α . Figure 2 shows the variation of a two-dimensional interval model with an uncertain parameter α . When $\alpha = 0$, the uncertainty set $\mathbf{X}^I(0)$ corresponds to a nominal vector of structural parameters.

Robust Control of Building Structures Under Uncertain Conditions, Fig. 2 Variation of uncertainty set of interval model

The robustness function $\hat{\alpha}$ for the design constraint of the seismic performance can be defined as

$$\hat{\alpha}(\mathbf{X}^c, f_c) = \max\{\alpha | f \leq f_c, f \in U(\mathbf{X}^c, \alpha)\} \quad (3)$$

where f , f_c , and $U(\mathbf{X}^c, \alpha)$ denote the objective function, the performance criterion value, and the set of the possible structural responses in the domain of the uncertainty set $\mathbf{X}^I(\alpha)$. In Eq. 3, the robustness function $\hat{\alpha}$ is the maximum value of the uncertain parameter α which satisfies the performance criterion $f \leq f_c$. If the nominal value $f(\mathbf{X}^c)$ of the objective function corresponding to the nominal design $\mathbf{X}^c$ violates f_c or just coincides with f_c without considering a safety factor, the robustness function $\hat{\alpha}$ is regarded as zero, which means that no variability due to the uncertainty of structural parameters can be allowed. If the relation $\hat{\alpha}_1(\mathbf{X}_1^c, f_c) > \hat{\alpha}_2(\mathbf{X}_2^c, f_c)$ holds, a design more robust than $\mathbf{X}_2^c$ can be achieved by $\mathbf{X}_1^c$.

Figure 3 illustrates the relationship between the robustness function and the feasible domain of structural design to satisfy the performance criterion $f \leq f_c$ for two-dimensional interval parameters. The robustness function $\hat{\alpha}$ is derived as the worst case of the objective function, i.e., the upper bound of the objective function $\bar{f}$ in $U(\mathbf{X}^c, \hat{\alpha})$. However, when the number of the combinations of uncertain parameters is extremely large, it may be hard to evaluate the worst case of the objective function reliably. For this reason, an efficient uncertainty analysis method is desired which can evaluate the upper bound of

Robust Control of Building Structures Under Uncertain Conditions, Fig. 3 Robustness function for performance criterion

the objective function considering the uncertainty of the structural parameters accurately and reliably.

As a simple example, let us consider a shear building model as a vibration model, as shown in Fig. 4, with viscous dampers in addition to masses and story stiffnesses. It is well recognized in the field of structural control and health monitoring that viscous damping coefficients c_i of dampers in a vibration model are quite uncertain compared to floor masses and structural stiffnesses. This is because most of such dampers possess high temperature and frequency dependencies and it is often difficult to restrain those properties into an acceptable range. By using a specific method for describing such uncertainty, the uncertain viscous damping coefficient of a damper can be expressed in terms of the nominal value $\tilde{c}_i$ and the unknown uncertainty level (band) α as shown in Fig. 5a (Takewaki and Ben-Haim 2005).

$$C(\alpha, \tilde{\mathbf{c}}) = \left\{ \mathbf{c} : \left| \frac{c_i - \tilde{c}_i}{\tilde{c}_i} \right| \leq \alpha, \quad i = 1, \dots, N \right\}, \alpha \geq 0 \quad (4a)$$

The inequality in Eq. 4a can be rewritten as

$$(1 - \alpha)\tilde{c}_i \leq c_i \leq (1 + \alpha)\tilde{c}_i \quad (4b)$$

This description is the same one used in the interval analysis (Moore 1966; Mullen et al. 1999; Koyluoglu and Elishakoff 1998).

Robust Control of Building Structures Under Uncertain Conditions, Fig. 4 Shear building model with uncertain viscous dampers

Another definition of uncertainty may be expressed by

$$C(\alpha, \tilde{\mathbf{c}}) = \left\{ \mathbf{c} : \sum_{i=1}^N \left| \frac{c_i - \tilde{c}_i}{\tilde{c}_i} \right|^2 \leq \alpha \right\}, \alpha \geq 0 \quad (4c)$$

The implication of Eq. 4c can be found in Fig. 5b. It seems that Eq. 4c is too mathematical oriented and does not express the vagueness of a real problem. However, unless a matter is expressed in a mathematical form, an uncertainty problem cannot be formulated. Furthermore, a simple model shown in Fig. 4 has been used to enable the drawing of a three-dimensional figure in Fig. 5b.

Figure 6 shows illustrative representation of the concept of info-gap robustness function. When the uncertainty level is α_2 , the response domain is just encircled by the permissible (or feasible) domain. In this case, the info-gap robustness function is given by α_2 .

Efficient Uncertainty Analysis Based on Interval Analysis

In this section, the URP (updated reference-point) method proposed originally for stochastic input is explained (Fujita and Takewaki 2011a). This method can be used as an efficient uncertainty analysis to obtain the robustness function $\hat{\alpha}$ explained in the previous section. Since the URP method takes full advantage of an approximation of first- and second-order Taylor series expansion in the interval analysis, the formulation of Taylor series expansion in the interval analysis and the achievement of second-order Taylor series expansion proposed by Chen et al. (2009) are explained briefly.

Robust Control of Building Structures Under Uncertain Conditions, Fig. 5 Description of uncertainty with info-gap model

R

Interval Analysis Using Taylor Series Expansion

An approximate objective function f^* using Taylor series expansion up to second order around the nominal model $\mathbf{X}^c$ can be expressed as

$$f^*(\mathbf{X}) = f(\mathbf{X}^c) + \sum_{i=1}^N f_{,X_i}(X_i - X_i^c) + \frac{1}{2} \sum_{i=1}^N \sum_{j=1}^N f_{,X_i X_j}(X_i - X_i^c)(X_j - X_j^c) \quad (5)$$

In Eq. 5, the notations $(\cdot)_{X_i}$ and $(\cdot)_{X_i X_j}$ denote first-order differentiation $\partial f(\mathbf{X}) / \partial X_i|_{X_i=X_i^c}$ and second-

order differentiation $\partial^2 f(\mathbf{X}) / \partial X_i \partial X_j|_{X_i=X_i^c, X_j=X_j^c}$ of the objective function at the nominal value. Therefore, $f_{,X_i}$ and $f_{,X_i X_j}$ correspond to the gradient of f and to the Hessian of f for the nominal model, respectively.

In order to evaluate the upper bound of f^* approximately, a basic theorem of “inclusion monotonic” in the interval analysis is often assumed. The theorem of “inclusion monotonic” is assumed in some of the previous studies on interval analysis, e.g., Chen et al. (2009). If the natural interval extension f^I of f is inclusion monotonic, the objective function f satisfies

Robust Control of Building Structures Under Uncertain Conditions, Fig. 6 Illustrative representation of concept of info-gap robustness function

$$\begin{aligned} & \{f(\mathbf{X}) : x_i \in X_i^I, i = 1, 2, \dots, N\} \\ & \subseteq f(X_1^I, X_2^I, \dots, X_N^I) \end{aligned} \quad (6)$$

The right-hand side of Eq. 6 denotes the interval (range) of the function f determined by the endpoint combinations. In other words, as long as the arguments of f are constrained between intervals (the lower and upper bounds a and b in $[a, b]$ are also called “intervals”), the variation of f for any interval parameter value within the intervals should be included in the range of values for the intervals. Based on the theorem of “inclusion monotonic,” the upper bound of f can be derived by iterative calculations with all endpoint combinations, i.e., the upper and lower bounds of interval parameters. However, when the number N of interval parameters is extremely large, this primitive approach needs much computational time and load caused by a large number of combination of interval parameters. Although the computational effort can be reduced effectively by the approximation of Taylor series expansion in Eq. 5, the number of iterative calculations with all endpoint combinations is the same with the

interval analysis method based on the theorem of “inclusion monotonic,” e.g., Dong and Shah (1987).

The approximation of Taylor series expansion enables the avoidance of iterative response analyses such as time-history analysis for evaluating the objective function. However, the computation of full elements of the Hessian matrix requires a huge computational load when N is large, especially for numerical sensitivity analysis, i.e., the finite difference analysis using gradient vectors. A simpler approach has therefore been proposed by Chen et al. (2009) where the non-diagonal elements of the Hessian matrix are neglected.

As a simple approximation, an objective function f^{**} using second-order Taylor series expansion with only diagonal elements can be rewritten as

$$\begin{aligned} f^{**}(\mathbf{X}) &= f(\mathbf{X}^c) \\ &+ \sum_{i=1}^N \left\{ f_{,x_i}(X_i - X_i^c) + \frac{1}{2} f_{,x_i x_i}(X_i - X_i^c)^2 \right\} \end{aligned} \quad (7)$$

From Eq. 7, the increment of the objective function can be evaluated by using first- and second-order Taylor series expansion as the sum of the increments of the objective function in each one-dimensional domain. The perturbation $\Delta f_i(\mathbf{X})$ of the objective function by the variation of the i -th interval parameter X_i can be described as

$$\Delta f_i(X_1^c, \dots, X_i, \dots, X_N^c) = f_{,X_i}(X_i - X_i^c) + \frac{1}{2} f_{,X_i X_i}(X_i - X_i^c)^2 \quad (8)$$

The validity of ignoring cross terms can be found in the reference (Fujita and Takewaki 2011). In Eq. 8, the interval extension of the one-dimensional perturbation can be derived as

$$\begin{aligned} \Delta f_i^I(X_1^c, \dots, X_i, \dots, X_N^c) \\ = \left[\min[\Delta f_i(X_1^c, \dots, \underline{X}_i, \dots, X_N^c), \Delta f_i(X_1^c, \dots, \bar{X}_i, \dots, X_N^c)], \right. \\ \left. \max[\Delta f_i(X_1^c, \dots, \underline{X}_i, \dots, X_N^c), \Delta f_i(X_1^c, \dots, \bar{X}_i, \dots, X_N^c)] \right] \end{aligned} \quad (9)$$

Equation 9 implies that the upper bound $\overline{\Delta f_i}$ of Eq. 7 can be derived by the comparison of Δf_i with structural parameter sets $\mathbf{X} = \{X_1^c, \dots, \underline{X}_i, \dots, X_N^c\}$ and $\mathbf{X} = \{X_1^c, \dots, \bar{X}_i, \dots, X_N^c\}$. Since Eq. 8 is a function of $\mathbf{X}$, it is natural to define an upper bound of that function. Finally, substituting $\overline{\Delta f_i}$ ($i = 1, \dots, N$) into Eq. 7, the interval extension of the approximate objective function f^{**} can be obtained as

$$\begin{aligned} f(\mathbf{X}^I) \approx \left[f(\mathbf{X}^c) + \left[\sum_{i=1}^N \underline{\Delta f_i}(X_i^I) \right], \right. \\ \left. f(\mathbf{X}^c) + \left[\sum_{i=1}^N \overline{\Delta f_i}(X_i^I) \right] \right] \end{aligned} \quad (10)$$

It is interesting to note that the number of calculations in Eq. 10 is reduced to $2N$ from 2^N in Eq. 7. However, it should also be mentioned that, because of the approximation by Taylor series expansion, the deterioration of accuracy cannot be avoided when the level of uncertainties of interval parameters is large.

Search Algorithm for Critical Combination of Interval Parameters

The approximation based on Taylor series expansion can reduce computational load dramatically in the interval analysis. However, it should be noted that the result by such approximation may (probably certainly) include errors. Furthermore, although some of the interval analysis methods

are based on “inclusion monotonic,” it is not necessarily appropriate to assume the monotonic variation of the objective function for dynamic responses. This is because a resonance (specific phenomenon in dynamic problems) could produce a non-monotonic response property. When the objective function has a non-monotonic property in $U(\mathbf{X}^c, \alpha)$, the extreme value of the objective function may occur not on the bound of interval parameters but in an inner feasible domain of interval parameters. Even in such a case, the robustness evaluation can be achieved by reanalyzing the structural response via a reliable response analysis for the estimated critical combination of interval parameters (worst case). In this section, an efficient search algorithm for the critical combination of interval parameters is explained which makes the approximate objective function maximum by using first- and second-order Taylor series expansion.

Consider Eq. 8 again. When the perturbation (or variation) $X_i - X_i^c$ of the structural parameter in Eq. 8 is denoted by ΔX_i , Eq. 8 can be transformed into

$$\Delta f_i(\Delta X_i) = \frac{1}{2} f_{,X_i X_i} \left(\Delta X_i + \frac{f_{,X_i}}{f_{,X_i X_i}} \right)^2 - \frac{f_{,X_i}^2}{2 f_{,X_i X_i}} \quad (11)$$

This transformation is just a simple mathematical transformation. From Eq. 11, it can be seen

Robust Control of Building Structures Under Uncertain Conditions, Fig. 7 Conceptual diagram of the URP method

that the increment of the objective function with respect to X_i is parabolic in the one-dimensional domain. By using Eq. 11, the target position can be found of the uncertain structural parameter X_1 which maximizes the objective function based on

the second-order Taylor series expansion. For instance, when $f_{,X_iX_i} < 0$ is satisfied, the target position $\hat{X}_i$ of the i -th interval parameter X_i which maximizes Eq. 11 can be derived explicitly as

$$\hat{X}_i = \begin{cases} X_i^c - f_{,X_i}/f_{,X_iX_i} & (|f_{,X_i}/f_{,X_iX_i}| \leq \Delta X_i) \\ X_i^c + \Delta X_i & (-f_{,X_i}/f_{,X_iX_i} \geq 0, |f_{,X_i}/f_{,X_iX_i}| > \Delta X_i) \\ X_i^c - \Delta X_i & (-f_{,X_i}/f_{,X_iX_i} < 0, |f_{,X_i}/f_{,X_iX_i}| > \Delta X_i) \end{cases} \quad (12)$$

The first case of Eq. 12 indicates that the critical value occurs in the inner domain. On the other hand, the second and third cases mean that the critical value occurs at the boundaries.

The target positions of the other interval parameters can be obtained successively in a similar way. The feature of the methodology explained here is that a possibility is considered of occurrence of the extreme value in an inner range of interval parameters and that only the first- and second-order sensitivities of the objective function are needed.

Equation 12 indicates that the target position of X_i can be derived by first- and second-order sensitivities $f_{,X_i}$, $f_{,X_iX_i}$ of the objective function with respect to X_i . For evaluating these sensitivities, it is needed to define a reference point. From the general point of view, it may be natural that the first- and second-order sensitivities with diagonal elements only are calculated at the reference

point of the nominal model. However, it is difficult to consider the influence of the interaction between the interval parameters in this approach. Fujita and Takewaki (2011a) developed the *updated reference-point method* (URP method) where the different computational procedure for the evaluation of first- and second-order sensitivities is applied. A detailed flow of the computation procedure of the URP method is explained below. The conceptual diagram of the URP method for two-dimensional interval parameters is shown in Fig. 7.

Step 1 Calculate the first-order sensitivities $f_{,X_i}$ ($i = 1, \dots, N$) of the objective function for the nominal model.

Step 2 Sort the absolute values $|f_{,X_i}|$ ($i = 1, \dots, N$) of the first-order sensitivities in descending order to give the priority to the parameter with the largest sensitivity. Sort also

the interval parameters as $\mathbf{X}_A = \{X_{A1}, \dots, X_{AN}\}$ corresponding to this.

Step 3 Calculate the second-order sensitivity of the objective function with respect to the interval parameter X_{Ak} . The second-order sensitivity $\partial^2 f / \partial X_{Ak}^2$ can be derived as a scalar value. When $k \geq 2$ holds, i.e., the reference point of the objective function has been updated, the first-order sensitivity of the objective function with respect to the interval parameter X_{Ak} should be calculated again.

Step 4 Derive the target position $\hat{X}_{Ak}$ of the interval parameter where the approximate objective function $f^{**}(\mathbf{X})$ is maximized. The problem in this step can be stated as

$$\begin{aligned} &\text{Find } \hat{X}_{Ak} \\ &\text{so as to maximize or minimize } f^{**}(\mathbf{X}) \\ &\text{subject to } X_{Ak} \in (X_{Ak})^I \\ &\text{where } X_{Al} \text{ is the current value } (l \neq k) \end{aligned} \quad (13)$$

Step 5 Update the set of interval parameters from current one X_{Ak} to $\hat{X}_{Ak}$.

Step 6 Update the corresponding system structural matrices such as $\mathbf{C}$ and $\mathbf{K}$ at the new reference point.

Step 7 Update k to $k + 1$. Repeat Step 2 through Step 6 until k becomes N .

Application to Building Structure with Passive Dampers

Any structural properties or responses, such as eigenvalue, static, and dynamic responses, can be employed as the objective function in the URP methods. From the viewpoint of seismic structural design, the applicability of the URP method to building structures with passive dampers is investigated as an example where the objective function is defined as maximum interstory drift for a set of recorded ground motions.

Structural Model with Passive Dampers and Selection of Uncertain Parameters

Consider an N -story planar shear building model, as shown in Fig. 8, with viscous dampers and their

Robust Control of Building Structures Under Uncertain Conditions, Fig. 8 Structural model with passive damper

supporting members. Let M_i , k_{fi} , c_{fi} , c_{di} , and k_{bi} ($i = 1, \dots, N$) denote the floor mass, the story stiffness of the frame, the structural damping coefficient, the damping coefficient of the passive damper, and the supporting member stiffness of the damper in the i -th story, respectively. It has been shown that the supporting member stiffness of dampers plays an important role in the optimal distribution of dampers (Fujita et al. 2010a). The frame stiffness distribution in the nominal model is shown in Fig. 9 ($N = 20$). The properties of structural parameter of the nominal model are shown in Table 1.

The equations of motion of the building with viscous passive dampers subjected to the horizontal ground motion can be expressed in time domain by

$$\begin{aligned} \mathbf{M}\ddot{\mathbf{u}}(t) \\ + (\mathbf{C} + \mathbf{C}_D)\dot{\mathbf{u}}(t) + (\mathbf{K} + \mathbf{K}_b)\mathbf{u}(t) = -\mathbf{M}\ddot{\mathbf{r}}_g(t) \end{aligned} \quad (14)$$

where $\mathbf{M}$, $\mathbf{C}$, $\mathbf{C}_D$, $\mathbf{K}$, and $\mathbf{K}_b$ are the system mass, structural damping, damper damping, structural stiffness, and supporting member

Robust Control of Building Structures Under Uncertain Conditions, Fig. 9 Story stiffness distribution

Robust Control of Building Structures Under Uncertain Conditions, Table 1 Structural parameters of main frame

	20-story building
Floor mass [kg]	$1,024 \times 10^3$

Supporting member stiffness [N/mm]	Ratio 1.0 to frame story stiffness
Structural damping ratio (stiffness-proportional damping)	0.02
Fundamental natural circular frequency with damper [rad/s] ^a	3.927

^aComplex eigenvalue analysis without dampers

stiffness matrices, respectively. Furthermore, $\mathbf{r} = \{1, \dots, 1\}^T$ is the influence coefficient vector. Assume that a viscous damper connected in series with its supporting member is treated as a detailed model in which a small lumped mass is allocated between the components of the dashpot and the spring. Then the components of the $\mathbf{K}$, $\mathbf{K}_b$, and $\mathbf{C}_D$ can be given by a linear combination of structural parameters k_{fi} , c_{di} , and k_{bi} ($i = 1, \dots, N$). The Newmark- β method ($\beta = 1/4$) is used to evaluate the maximum interstory drift.

The structural parameters $\mathbf{c}_d = \{c_{di}\}$, $\mathbf{k}_b = \{k_{bi}\}$, and $\mathbf{k}_f = \{k_{fi}\}$ are employed as interval parameters. The interval parameters of these uncertain

structural parameters are described with an uncertain parameter α by

$$\begin{aligned} \mathbf{c}'_d &= [\mathbf{c}_d^c - \alpha \Delta \mathbf{c}_d, \mathbf{c}_d^c + \alpha \Delta \mathbf{c}_d] \\ \mathbf{k}'_b &= [\mathbf{k}_b^c - \alpha \Delta \mathbf{k}_b, \mathbf{k}_b^c + \alpha \Delta \mathbf{k}_b] \\ \mathbf{k}'_f &= [\mathbf{k}_f^c - \alpha \Delta \mathbf{k}_f, \mathbf{k}_f^c + \alpha \Delta \mathbf{k}_f] \end{aligned} \quad (15a, b, c)$$

The uncertainty levels of interval parameters $\mathbf{X}' = \{\mathbf{c}'_d, \mathbf{k}'_b, \mathbf{k}'_f\}$ are given by $\boldsymbol{\varepsilon} = \{\varepsilon_i\}$ ($i = 1, \dots, 3N$) defined by

$$\varepsilon_i = \begin{cases} \Delta c_{di}/c_{di}^c = 0.3 & (i = 1, \dots, N) \\ \Delta k_{bi-N}/k_{bi-N}^c = 0.3 & (i = N+1, \dots, 2N) \\ \Delta k_{fi-2N}/k_{fi-2N}^c = 0.1 & (i = 2N+1, \dots, 3N) \end{cases} \quad (16)$$

Equation 16 assumes that the degrees of uncertainties of interval parameters are constant for all stories on the same structural properties in the following numerical examples.

Recorded Ground Motions

El Centro NS 1940, Taft EW 1952, and Hachinohe NS 1968 are used as representative recorded ground motions, whose maximum ground velocities are normalized as 0.5 [m/s]. These earthquake ground motions are often used in the structural design (level 2 of large earthquake ground motion) of high-rise and base-isolated buildings in Japan. Figure 10a–c shows the normalized recorded ground motions.

Robustness Function for Various Damper Distributions

In this section, the robustness functions defined by Eq. 3 for various damper distributions are evaluated by the URP method. Figure 11 shows the comparison of maximum interstory drifts of the building structure without dampers for three recorded ground motions. It may be observed from Fig. 11 that the interstory drift is maximized at upper stories above the 15th floor. For enhancing the seismic performance of the building structure, let us consider three different

Robust Control of Building Structures Under Uncertain Conditions, Fig. 10 Normalized recorded ground motions (a) El Centro NS (1940), (b) Taft EW (1952), (c) Hachinohe NS (1968)

Robust Control of Building Structures Under Uncertain Conditions, Fig. 11 Maximum interstory drift without dampers

damper distributions: (a) uniform distribution, (b) added only from 11th to 20th story, and (c) optimum distribution. In these various damper distributions, the total quantity of damping coefficients of the viscous dampers is given by a constant value as shown in Table 1. Figure 12 shows the comparison of the maximum interstory drifts with three different damper distributions shown in Fig. 13.

The optimum damper distribution has been derived by the optimization algorithm developed in the reference (Fujita et al. 2010b) to minimize the maximum amplitude of interstory-drift transfer function.

Figure 14a–c shows the robustness functions with respect to the constraint on the maximum interstory drift for the three representative recorded ground motions. These figures can be obtained by using the method in section “Efficient Uncertainty Analysis Based on Interval Analysis” and evaluating the maximum interstory drift for various values of $\hat{\alpha}$. The maximum interstory drift of the nominal model without uncertainty is shown in Fig. 14a–c at the uncertainty parameter $\hat{\alpha} = 0$. By comparing these nominal values of the objective function for various damper distributions, it is understood that the most preferable response reduction can be obtained by the damper distribution from 11th to 20th story in El Centro NS (1940) and Hachinohe NS (1968). On the other hand, the most preferable response reduction can be obtained by the optimal damper distribution in

Taft EW (1952). Since the optimal damper distribution is aimed at suppressing the maximum amplitude of interstory-drift transfer function at the fundamental natural circular frequency, the drastic response reduction can be achieved for the excitation, such as Taft EW (1952), whose predominant frequency is resonant to the fundamental natural circular frequency of the objective building structure. It can be observed from Fig. 14b that if the performance criterion with respect to the maximum interstory drift is given by 0.03 [m], the robustness function $\hat{\alpha}$ is nearly

0.8 for the optimal damper distribution, while nearly 0.4 for the 11th–20th story distribution. From this comparison, it can be concluded that a large robustness can be obtained by the optimal damper distribution.

From the viewpoint of seismic structural design, the total quantity of added dampers may be a principal design parameter. In the general design procedure, the total quantity of dampers is determined based on the requirement whether the dynamic responses satisfy the constraints with a certain safety factor ρ . However, it is often ambiguous whether the values of these safety factors are appropriate or not. On the other hand, such total damper quantity can be derived in a more logical manner by using the “robustness function” for the structural uncertainty. Figure 15a shows the conceptual diagram of the redesign approach for determining the total damper quantity for a robust building structure, which can be derived by varying the robustness function with respect to the total damper quantity. The thick curve can be drawn by evaluating the dynamic response for various total quantities of dampers (nominal parameters). In Fig. 15a, when the performance criterion f_c and the robustness function $\hat{\alpha}$ are given (0, 0.5, 1.0), an appropriate

Robust Control of Building Structures Under Uncertain Conditions, Fig. 12 Comparison of maximum interstory drift with various damper distributions

Robust Control of Building Structures Under Uncertain Conditions, Fig. 13 Various damper distributions: (a) uniform, (b) 11th–20th story, (c) optimum

Robust Control of Building Structures Under Uncertain Conditions, Fig. 14 Comparison of robustness functions for various damper distributions. (a) El Centro NS (1940), (b) Taft EW (1952), (c) Hachinohe NS (1968)

total damper quantity can be found (Design 1, 2, 3). If the value of $\hat{\alpha}$ is assumed to be large, the total damper quantity will increase and a large robustness can be achieved. Figure 15b illustrates the relation of total quantities of passive dampers for the robustness function representation and the safety factor representation (Design 4). It can be observed that the robustness function of Design 4 with a safety factor ρ is between 0.5 and 1.0. A clear understanding may be possible of the meaning of the safety factor in terms of the structural robustness.

Figure 16 shows the degree of robustness of building structures with different damper distributions in terms of different robustness functions. If the maximum interstory drift is specified as 0.03 [m], the building structure with the optimum

damper distribution exhibits the maximum robustness. The building structure with a uniform damper distribution is the second and that with the 11–20th story distribution is the third.

Application to Base-Isolated Building with Hysteretic Response

Estimation of the Variation of the Objective Function by Second-Order Taylor Series Expansion

If the critical combination of interval parameters maximizing the objective function can be predicted, it becomes possible to evaluate the robustness accurately. Therefore, the Taylor

Robust Control of Building Structures Under Uncertain Conditions, Fig. 15 Redesign of total quantity of passive dampers for robust structures, (a) total quantity of dampers for no robustness, small robustness and large

robustness for a given performance criterion, (b) total quantity of dampers for the robustness function representation and the safety factor representation

Robust Control of Building Structures Under Uncertain Conditions,

Fig. 16 Degree of robustness in terms of different robustness function

series approximation with diagonal elements only is used to predict this critical combination. Consider the variation $\Delta f_i(dX_i)$ for X_i and let us regard $dX_i = X_i - X_i^c$ as a variable satisfying $-\Delta \bar{X}_i \leq dX_i \leq \Delta \bar{X}_i$. Then the variation $\Delta f_i(dX_i)$ can be rewritten as

$$\Delta f_i(dX_i) = \frac{1}{2} f_{,X_i X_i} (dX_i + f_{,X_i} / f_{,X_i X_i})^2 - f_{,X_i}^2 / 2 f_{,X_i X_i} \quad (17)$$

This is the same as Eq. 11. The function defined by Eq. 17 is a quadratic function and

Robust Control of Building Structures Under Uncertain Conditions, Fig. 17 Flowchart of URP method. (a) Second-order Taylor series approximation, (b) response surface method (RSM)

the value dX_i maximizing or minimizing Δf can be obtained explicitly. Consider the case satisfying $f_{,X_iX_i} < 0$. If the notation $\Delta \bar{X}_i = \Delta \underline{X}_i = \Delta X_i$ is

introduced, the interval parameter maximizing Δf_i can be obtained as follows:

$$\hat{X}_i = \begin{cases} X_i^c - f_{,X_i}/f_{,X_iX_i} & (|f_{,X_i}/f_{,X_iX_i}| \leq \Delta X_i) \\ X_i^c + \Delta X_i & (-f_{,X_i}/f_{,X_iX_i} \geq 0, |f_{,X_i}/f_{,X_iX_i}| > \Delta X_i) \\ X_i^c - \Delta X_i & (-f_{,X_i}/f_{,X_iX_i} < 0, |f_{,X_i}/f_{,X_iX_i}| > \Delta X_i) \end{cases} \quad (18)$$

This is the same as Eq. 12. The evaluation of first- and second-order sensitivities $f_{,X_i}$ and $f_{,X_iX_i}$ is made at the nominal model (reference point). It should be noted that the correlation among interval parameters is not taken into account. Here a method called the URP (updated reference-point) method (Fujita and Takewaki 2011a) is used. This method changes the reference point step by step. The flowchart for finding the upper bound of the objective function is shown in Fig. 17a.

Estimation of the Variation of the Objective Function by Response Surface Approach

In the method using Taylor series expansion as explained in previous sections, the accuracy of the robustness evaluation depends directly on the reliability of the numerical sensitivity analysis. For this reason, when the evaluation of numerical sensitivities has some difficulties resulting from the elastic-plastic structural property of isolators, another URP method should be introduced where the variation of the objective function is

Robust Control of Building Structures Under Uncertain Conditions,

Fig. 18 Base-isolated structural model (Fujita and Takewaki 2012a)

estimated using a kind of response surface methods (RSM). RSM is well known as a statistical response evaluation technique which can provide the continuous variation of the objective function by several response samplings. Here three response values $\bar{f}$ evaluated at the nominal, lower and upper ends of an interval parameter X_i are used, and the following second-order polynomial model is introduced:

$$f(X_i) = a_1 + a_2X_i + a_3X_i^2 \quad (19)$$

In Eq. 19 $a_i (i = 1, 2, 3)$ are unknown variables derived from reference responses (some sampling points). By using this approximation of the objective function, the URP method can be applied to the uncertainty analysis as shown in section “[Estimation of the Variation of the Objective Function by 2nd-Order Taylor Series Expansion](#).” Figure 17b shows the flowchart of the URP method using RSM.

Application of URP Method to Base-Isolated Building

Application of the URP method to a base-isolated building model is shown in this section. The validity of the URP method using second-order Taylor series approximation (section “[Estimation of the Variation of the Objective Function by 2nd-Order](#)”

[Taylor Series Expansion](#)”) and RSM (section “[Estimation of the Variation of the Objective Function by Response Surface Approach](#)”) is demonstrated through the comparison with the other method (Monte Carlo Simulation (MCS)). Although the number of interval parameters shown later is large in this simulation, the response analyses are performed for randomly selected combination of endpoints of interval parameters.

Modeling of Base-Isolated Buildings and Uncertainty of Structural Parameters

Consider an N -story base-isolated shear building model as shown in Fig. 18. A simple model is used here to present an essential feature of the robustness evaluation method. Since the use of natural rubber bearings (NRB) only as isolator elements may lead to a higher level of acceleration at the top story, both NRB and lead rubber bearings (LRB) are used here. Furthermore, an additional damping in the base-isolation story is to be given by oil dampers.

It is necessary to take into account the response variability (robustness) of the building under earthquake ground motions due to the variability of mechanical properties of isolators, dampers, and superstructures. Table 2 shows an example of variability ratios (variable band) of isolators of NRB and LRB.

Robust Control of Building Structures Under Uncertain Conditions, Table 2 Variability ratio of structural properties of isolators (NRB and LRB) (Fujita and Takewaki 2012a)

Isolator	Structural parameter	Bound	Manufacturing error (%)	Temperature dependency (%)	Aging deterioration (%)
NRB (natural rubber bearing)	Elastic shear modulus	Upper	+10	+6	+10
		Lower	−10	−5	0
LRB (lead rubber bearing)	Plastic stiffness	Upper	+10	+6	+11
		Lower	−10	−5	0
	Hysteretic strength	Upper	+10	+23	0
		Lower	−10	−21	0

Interval variables in this example are the damping coefficient c_0 and elastic shear stiffness k_0 of NRB, the plastic shear stiffness K_d and elastic shear stiffness K_e of LRB, and the damping coefficient vector $\mathbf{c}_f$ and the horizontal stiffness vector $\mathbf{k}_f$ of the superstructure. The set of interval variables is denoted by

$$\mathbf{X}^I = \{c_0^I, k_0^I, K_d^I, K_e^I, \mathbf{c}_f^I, \mathbf{k}_f^I\} \quad (20)$$

For members with the same properties, it may be appropriate to assign the same variability in each group of members in a building. It should be noted that the present formulation is applicable to such realistic case.

Let us define the ratios of the upper and lower variations of interval variables to the corresponding nominal values.

$$\bar{\alpha} = \left\{ \frac{\Delta \bar{c}_0}{c_0^c}, \frac{\Delta \bar{k}_0}{k_0^c}, \frac{\Delta \bar{K}_d}{K_d^c}, \frac{\Delta \bar{K}_e}{K_e^c}, \frac{\Delta \bar{c}_{f_1}}{c_{f_1}^c}, \dots, \frac{\Delta \bar{k}_{f_1}}{k_{f_1}^c}, \dots \right\} \quad (21a)$$

$$\alpha = \left\{ \frac{\Delta c_0}{c_0^c}, \frac{\Delta k_0}{k_0^c}, \frac{\Delta K_d}{K_d^c}, \frac{\Delta K_e}{K_e^c}, \frac{\Delta c_{f_1}}{c_{f_1}^c}, \dots, \frac{\Delta k_{f_1}}{k_{f_1}^c}, \dots \right\} \quad (21b)$$

The structural property of a 20-story base-isolated building ($N = 20$) is summarized in the following. The floor mass per story is $1,024 \times 10^3$ (kg). This corresponds to $32 \text{ m} \times 32 \text{ m}$ floor plan ($1,000 \text{ kg/m}^2$). The floor mass per story is denoted by m , and the lowest mode of vibration of the super building with fixed base-isolation story is given by a straight line. Then the story stiffness can be expressed as

$$k_{f_i} = \frac{1}{2} \{N(N+1) - i(i-1)\} m \omega_1^2 \quad (i = 1, \dots, N) \quad (22)$$

where ω_1 is the fundamental natural circular frequency of the super building with fixed base-isolation story and is given by 3.93 [rad/s] (natural period = 1.6 [s]). The super building is assumed to behave elastically. The damping coefficients of the super building are given by stiffness-proportional damping with a lowest-mode damping ratio $h = 0.02$.

In the design of the base isolator, the diameter, thickness, and shear modulus have to be determined. The required conditions are that (1) the stress under dead load is within an allowable value and (2) the deformation capacity and the fundamental natural period are appropriate. When only NRB isolators are used, the horizontal stiffness k_0 of the base-isolation story is often determined by specifying the natural circular frequency of the model with the rigid super building. On the other hand, since LRB isolators have the elastic–plastic characteristic, it may be difficult to derive k_0 for the target natural frequency of the base-isolated building. Table 3 shows the property of NRB and LRB isolators of the example model. The fundamental natural circular frequency of this base-isolated building is 1.16 [rad/s], i.e., natural period = 5.40 [s]. The additional damping coefficient of the dampers in the base-isolation story is given by specifying the damping ratio of the model with a rigid super building as 0.1 .

Input Ground Motions

Since it is well known that base-isolated buildings are vulnerable for long-period and

Robust Control of Building Structures Under Uncertain Conditions, Table 3 Parameters of isolators of base-isolated building (Fujita and Takewaki 2012a)

	NRB	LRB
Diameter of rubber [mm]	1100	
Total rubber thickness [mm]	252	
Shear modulus of rubber [N/mm ²]	0.390	0.385
Diameter of lead plug [mm]	200	
Shear modulus of lead plug [N/mm ²]	0.588	
Total number of isolators	8	15

long-duration ground motions (Ariga et al. 2006; Takewaki 2008; Takewaki et al. 2012), six long-period ground motions are used in this example. Tomakomai EW motion is famous in Japan as the first one which brings attention to the long-period ground motion in the design of super high-rise buildings and base-isolated buildings (Ariga et al. 2006). The other ones are the ground motions recorded during the 2011 Tohoku earthquake and its aftershocks. These ground motions are scaled to the same maximum ground velocity = 0.5 [m/s]. This scaling is used in the structural design of high-rise buildings in Japan. Figure 19a–e, f presents the time histories of acceleration and velocity of those ground motions. The velocity response spectra are shown in Fig. 20.

Interval Analysis for Drift of Base-Isolation Story

The uncertainty analysis is shown here for the maximum drift of base-isolation story. The level of variability in Eq. 20 is given by

$$\bar{\alpha} = \begin{cases} 0.3 & (i = 1) \\ 0.26 & (i = 2) \\ 0.27 & (i = 3) \\ 0.26 & (i = 4) \\ 0.1 & (i = 5, \dots, N + 4) \\ 0.05 & (i = N + 5, \dots, 2N + 4) \end{cases}, \quad (23)$$

$$\underline{\alpha} = \begin{cases} 0.3 & (i = 1) \\ 0.15 & (i = 2) \\ 0.15 & (i = 3) \\ 0.3 & (i = 4) \\ 0.1 & (i = 5, \dots, N + 4) \\ 0.05 & (i = N + 5, \dots, 2N + 4) \end{cases}$$

where i denotes the interval variable number. The case of $i = 1$ corresponds to the damping coefficient of oil dampers in the base-isolation story. The case of $i = 2$ indicates the elastic shear stiffness k_0 of the NRB. In addition, the case of $i = 3$ gives plastic stiffness K_d of LRB, and the case of $i = 4$ corresponds to elastic shear stiffness K_e of LRB. Here intervals of k_0 and K_d are treated to be unsymmetrical in increasing and decreasing directions. This is due to the aging effect (hardening) of isolators. Furthermore, the case of $i = 5, \dots, N + 4$ provides the damping coefficients $\mathbf{c}_f$ of the super building, and the case of $i = N + 5, \dots, 2N + 4$ corresponds to the story stiffness $\mathbf{k}_f$ of the super building.

Figure 21 shows the upper bounds of the maximum drift of the base-isolation story compared for various methods (URP methods with second-order Taylor series approximation/with RSM and the Monte Carlo Simulation (MCS)). As explained before, the difference between the URP method with second-order Taylor series approximation and that with RSM is how to estimate the variation of the objective function. In the former one, the numerical sensitivities, i.e., the gradient vector and the Hessian matrix, of the objective function are needed. On the other hand, in the latter one, a kind of RSM is applied where appropriate response samplings are made and the gradient vector and the Hessian matrix are evaluated from the constructed approximate function.

Figure 22 illustrates the comparison of the hysteresis loop and time history of drift in the base-isolation story for models with nominal parameters and critical parameters under Shinjuku NS (2011/03/12). This ground motion is a result of the aftershock for March 11, 2011,

Robust Control of Building Structures Under Uncertain Conditions, Fig. 19 Recorded ground motions (Max. Vel. is 0.5 m/s) (Fujita and Takewaki 2012a)

Robust Control of Building Structures Under Uncertain Conditions,

Fig. 20 Velocity response spectrum ($h = 0.05$) (Fujita and Takewaki 2012a)

Robust Control of Building Structures Under Uncertain Conditions, Fig. 21 Comparison of maximum interstory drift of base-isolation story derived by URP method with MCS (Fujita and Takewaki 2012a)

Tohoku (Japan) earthquake. It can be observed that the critical parameters certainly give a larger response than the nominal parameters.

Figure 23 presents the upper bounds of the maximum top-story floor acceleration by the interval analysis with various methods (URP methods with second-order Taylor series approximation/with RSM and the Monte Carlo simulation). It can be observed from Fig. 23 that the level of variability of the maximum value into the increasing side derived by the URP method with RSM is larger than that of second-order Taylor series approximation. In other words, while the URP method with RSM provides a definite upper bound for the Monte Carlo simulation, the URP method with second-order Taylor series approximation does not necessarily assure the upper bound. This may result from the difficulty

in the sensitivity analysis in the process of the second-order Taylor series approximation for elastic-plastic responses.

Summary

The design of building structures with greater robustness and reliability can be achieved by taking into account the input disturbance uncertainties and structural parameter uncertainties (Takewaki et al. 2012). In order to get a reliable design with greater robustness, the introduction and definition of robustness are essential.

A robustness function for the constraint on dynamic response of building structures with passive dampers subjected to ground motions has been defined based on the info-gap decision

Robust Control of Building Structures Under Uncertain Conditions,

Fig. 22 Comparison of hysteresis loop and time history of drift in base-isolation story for models with nominal parameters and critical parameters under Shinjuku NS (2011/03/12) (Fujita and Takewaki 2012a)

Robust Control of Building Structures Under Uncertain Conditions, Fig. 23 Comparison of maximum top-story acceleration derived by URP method with MCS (Fujita and Takewaki 2012a)

theory (Ben-Haim 2001). For evaluating the reliable robustness, an efficient uncertainty analysis methodology for the robustness evaluation of a damped structure has been explained which is aimed at finding the upper bound of dynamic response under uncertainties of structural parameters.

In the explained uncertainty analysis method, a model of uncertain parameters has been defined by using an interval model. Although the basic

theorem of “inclusion monotonic” is assumed in some of the interval analyses proposed so far, the critical combination of interval parameters in a feasible domain, not only on the bounds but also in an inner domain of interval parameters, has been derived explicitly by using the explained method. By evaluating the extreme value of the objective function via the approximation of second-order Taylor series expansion, the upper bound of the objective function can be

obtained straightforwardly for the predicted structural parameter set. To evaluate the upper bound of the objective function more accurately within a reasonable task, the URP (updated reference-point) method has been introduced where the reference point to calculate first- and second-order sensitivities has been updated according to the variation of uncertain structural parameters.

Numerical examples using the robustness function has been presented for a 20-story planar shear building including passive viscous dampers with supporting members by applying the URP method. A detailed comparison of the robustness of the structures where the additional dampers have been distributed (a) uniformly, (b) from 11th to 20th story, and (c) optimally has been conducted for representative recorded ground motions. The optimum damper distribution has been derived by the optimization algorithm developed to minimize the maximum amplitude of interstory-drift transfer function. By comparing the robustness functions among the various damper distributions, the large robustness can be obtained in the design of optimal damper distribution especially for the excitation whose predominant frequency is resonant to the fundamental natural frequency of the building structure.

An approximate contour plot of the robustness function with respect to a varied total damper quantity has been constructed. By comparing the contour plots of the robustness function for various damper distributions, a total damper quantity can be derived which satisfies the performance criterion under the uncertainty of the structural parameters. It has also been shown that it is possible to clarify the relation of total quantities of passive dampers for the robustness function representation and the safety factor representation. It is expected that this leads to a more robust damper design.

Application of the URP method to the base-isolated building model with hysteretic responses has been shown. The validity of the URP method using second-order Taylor series approximation and RSM (response surface method) is demonstrated through the comparison with the other method (Monte Carlo Simulation (MCS)).

Introduction

The design of structures, with the help of numerical procedures, is one of the most challenging engineering tasks. The structure has to withstand

all dead loads, live loads, and unpredictable events as earthquakes. Earthquake analysis itself is, due to the high lack of information, sophisticated. The numerical simulation of these structures needs advanced methods to capture the nonlinear dynamic behavior. The recent advancements in the field of finite element analysis (FEA) enable the possibility to simulate the deterministic structural behavior.

But a realistic simulation of structures needs to consider uncertainty for actions and resistances. Hence, the realistic consideration of earthquake loads needs to describe the uncertainty of, e.g., intensity and duration of the earthquake. Therefore, uncertainty models are necessary, and this contribution is focused on the parameterized description of uncertainty by using uncertain variables; see section “[Uncertainty Modeling](#).” A well-established model to describe uncertainty is a random variable, which can model the uncertainty characteristic variability.

But the unfulfillable conditions to apply random variables in an engineering application need models to describe epistemic uncertainty, as expert knowledge and small sample sizes; therefore, the uncertainty model fuzziness is used. The combination of both models, fuzzy probability-based randomness, combines the advantages and is a sophisticated uncertainty model. The necessary numerical algorithms are formulated in section “[Uncertain Structural Analysis](#).”

The consideration of uncertain variables in processes, as earthquake analysis, needs the formulation of algorithms to gather the additional time dependency. This extension of the uncertain analysis to uncertain earthquake analysis is shown in section “[Earthquake Analysis Under Consideration of Uncertain Data](#).” A specific aspect is the numerical efficiency of the approaches; therefore, discussion about the possibility to decrease the computational costs is included.

There are several definitions of the robustness of structures. This contribution uses a robustness measure, based on the comparison of the uncertainty of the input quantities and the output

quantities; see section “[Robustness](#).” The measure applies information reducing measures to quantify the amount of uncertainty of the quantities. This computation allows a relative statement of the robustness of the structure (for the given loads).

The main idea of this contribution is to design robust structures under consideration of earthquake loads. The synthesis of uncertainty (to quantify the robustness of structures) and design of structures under consideration of time-dependent responses (earthquake-induced processes) are described in section “[Numerical Design of Processes with Uncertain Parameters](#).” The design of structures can be done by simply observing several variants or by using optimization technologies. Another possibility, especially in an early stage of design, is the solution of inverse problems. The focus of this contribution is on parameterized optimization, as design technology, with the objective to find robust structures. This is known as robust design optimization (RDO). The consideration of uncertain design variables is solved by a split into deterministic design and uncertain a priori variables. This section shows the necessary mathematical formulations for optimization under consideration of uncertain variables (design and other variables can be uncertain) and a possibility for numerical implementation, by using the numerical analysis concepts for uncertain data, shown in section “[Uncertain Structural Analysis](#).”

This contribution is focused on numerical procedures for robust design, including uncertainty modeling and computation, for structures under earthquake loads. The example shows the applicability of the approaches; see section “[Example](#).”

Uncertainty Modeling

Uncertainty models can be categorized in two main fields. On the one hand, there are basic uncertainty models, and on the other hand, there are generalized (polymorphic) uncertainty models (Möller and Beer 2004; Beer et al. 2013).

Robust Design Optimization for Earthquake Loads,

Fig. 1 Visualization of a normalized fuzzy set and an α -level

With generalized uncertainty models, more than one uncertainty characteristic can be considered. This contribution will present fuzziness and randomness as basic models and furthermore fuzzy probability-based randomness as a polymorphic model (see Pannier et al. 2013).

Fuzziness

Fuzzy Set

The idea of fuzzy sets is the gradual weighting of a crisp subset $A \in \mathbb{R}$. The crisp subset is defined by the characteristic function

$$\xi_A : \mathbb{R} \rightarrow \{0; 1\}, x \mapsto \begin{cases} 1, & x \in A \\ 0, & x \notin A. \end{cases} \quad (1)$$

The gradual weighting can be found by the mapping $\mu : A \rightarrow [0, 1]$, i.e., the set of ordered pairs

$$\{(x, \mu(x)) | x \in X \subseteq \mathbb{R}, \mu(x) \geq 0\}. \quad (2)$$

This mapping is the membership function (or the fuzzy set of A). If the membership function μ satisfies $\sup_{a \in A} \mu(A) = 1$, then μ is called a normalized fuzzy set, e.g., see Fig. 1. The membership function can be interpreted as the possibility of occurrence. The uncertainty model fuzzy variable can be used, if reliable information is spare or if only subjective information, as expert knowledge, is available.

Cartesian Product

The membership function of a multidimensional fuzzy set $\mathcal{F}(A)$ is defined by the Cartesian product

Robust Design Optimization for Earthquake Loads,
Fig. 2 Cartesian product of two fuzzy variables

$$\tilde{K} = (\tilde{A}_1 \times \cdots \times \tilde{A}_n), \quad (3)$$

yielding to the membership function

$$\begin{aligned} \mu_{\tilde{K}} : \mathbb{R}^n &\rightarrow [0; 1] \\ &: ((x_1, \dots, x_2) \mapsto \min(\mu_{\tilde{A}_1}(x_1); \dots; \mu_{\tilde{A}_n}(x_1))). \end{aligned} \quad (4)$$

A visualization for a two-dimensional fuzzy set is shown in Fig. 2. In general, the set of all fuzzy sets of A is denoted as $\mathcal{F}(A)$.

α -Level Discretization

In view of a numerical treatment, it is necessary to discretize the fuzzy set $\tilde{A}$ into α -level cuts. Due to the usage of normalized fuzzy sets, the discretization needs to be applied for $\alpha \in (0, 1]$. The α -level cut

$$\tilde{A}_\alpha = \{x \in \mathbb{R} \mid \mu_{\tilde{A}}(x) \geq \alpha\} \quad (5)$$

is a crisp subset $\tilde{A}_\alpha \subseteq \mathbb{R}$. Summarizing, each fuzzy set $\tilde{A}$ is uniquely determined by the family of α -level cuts, that is,

$$\tilde{A} = (\tilde{A}_\alpha)_{\alpha \in (0;1]}. \quad (6)$$

The points of view of this contribution are convex fuzzy variables. Convexity is given, if all α -level cuts are convex, that means for $x_1, x_2 \in \mathbb{R}$ and $\lambda \in [0; 1]$, it holds

$$\mu_{\tilde{A}}(\lambda \cdot x_2 + (1 - \lambda) \cdot x_1) \geq \min(\mu_{\tilde{A}}(x_1), \mu_{\tilde{A}}(x_2)). \quad (7)$$

An example of a convex fuzzy set is the triangular-shaped fuzzy variable $\langle q, r, s \rangle$, with $q, r, s \in \mathbb{R}$ holding

$$\begin{aligned} \langle q, r, s \rangle : \mathbb{R} &\rightarrow [0, 1] \\ : x &\mapsto \begin{cases} \frac{1}{r-q} \cdot (x-q) & \text{for } q < x \leq r, \\ \frac{1}{s-r} \cdot (s-x) & \text{for } r < x \leq s, \\ 0 & \text{otherwise.} \end{cases} \end{aligned} \quad (8)$$

Randomness

The probability space (Ω, Σ, P) is composed of a set of elementary events Ω , a σ -algebra Σ and a probability measure P (Pannier et al. 2013). The sample space Ω contains all possible elementary events ω . For continuous random variables, e.g., $\Omega \in \mathbb{R}$, the Borel σ -algebra, denoted by $\mathcal{B}(\mathbb{R})$, contains all possible intervals $I \subseteq \mathbb{R}$. The probability measure P assigns for each event $s \in \Sigma$ a real value in $[0,1]$, representing the probability of s . The probability measure is the mapping

$$P : \Sigma \rightarrow [0, 1], \quad (9)$$

holding the axioms of Kolmogorov:

$$(I) \quad \forall A \in \Sigma : 0 \leq P(A) \leq 1 \quad (10)$$

$$(II) \quad P\phi = 1 - P(\Omega) = 0 \quad (11)$$

$$(III) \quad P\left(\bigcup_{i \in \mathbb{N}} A_i\right) = \sum_{i \in \mathbb{N}} P(A_i), \quad (12)$$

with $(A_i)_{i \in \mathbb{N}} \in \Sigma^{\mathbb{N}}$, $A_i \cap A_j (i \neq j, i, j \in \mathbb{N})$.

For a real-valued observation space, the random variable X is $X : \Omega \rightarrow \mathbb{R}$ that satisfies the condition

$$\forall I \in \Sigma : X^{-1}(I) := \{\omega \in \Omega; X(\omega) \in I\} \in \Sigma. \quad (13)$$

The probability measure P_X , related to the random variable X , is defined as

$$\begin{aligned} P_X : \mathcal{B}(\mathbb{R}) &\rightarrow [0; 1] : I \mapsto P_X(I) = P_X(X^{-1}(I)) \\ &= P(\{\omega \in \Omega | X(\omega) \in I\}). \end{aligned} \quad (14)$$

The distribution of a random variable X can be described by a cumulative distribution function (CDF) F_X (see Fig. 3) and the related probability density function (PDF) f_X , respectively, yielding the probability for an interval I ,

$$P_X(I) = \int_I f_X(t) dt = \int_{x_l}^{x_r} f_X(t) dt \text{ with } I = [x_l; x_r]. \quad (15)$$

The CDF F_X contains no information of the underlying probability space, there is just information about the distribution. Therefore, the CDF is analyzed for intervals $I = [-\infty; x]$, such that

$$F_X(x) = \int_{-\infty}^x f_X(t) dt. \quad (16)$$

For a continuous f_X , the probability of an interval $I = [x_l; x_r]$ is

$$F_X(I) = F_X(x_r) - F_X(x_l). \quad (17)$$

The uncertainty model randomness can be used to model large data sets showing the uncertainty characteristic variability. Furthermore, the

**Robust Design
Optimization for
Earthquake Loads,**
Fig. 3 Visualization of a
random variable

samples need to be independent and identically distributed. Due to small sample sizes and the mostly unfulfilled i.i.d. paradigm, the applicability of random variables for engineering tasks is limited.

Fuzzy Probability-Based Randomness (fp-r)

Definition

A type of a polymorphic uncertainty model is the fuzzy probability-based randomness, taking variability and incompleteness into account. For fuzzy probability-based random variables, the probability measure P of the random number, Eq. 9, is defined as an evaluated set of probability functions. This means that every event is represented by a fuzzy value and not by a real number. The fuzzy probability space is the triple $(\Omega, \Sigma, \hat{P})$. Ω and Σ are the same as in the random number definition. The fuzzy probability $\hat{P}$ is a family of mappings

$$\hat{P} = (\hat{P}_\alpha)_{\alpha \in (0,1]}, \quad (18)$$

where $\hat{P}_\alpha$ assigns to each $A \in Z$ an interval $[\hat{P}_{\alpha,1}(A), \hat{P}_{\alpha,r}(A)]$, such that

$$0 \leq \hat{P}_{\alpha,1}(A) \leq \hat{P}_{\alpha,r}(A) \leq 1 \quad (19)$$

holds. The relating measurable mapping $X : \Omega \rightarrow \mathbb{R}$ is introduced as a fuzzy probability-based random variable. To describe a cumulative distribution function, it is necessary to define the set

$$(F_X)_\alpha := \{G : \mathbb{R} \rightarrow [0;1] \text{ cdf} \mid \forall x \in \mathbb{R} : \hat{P}_{\alpha,l}(X^{-1}((-\infty; x])) \leq G(x) \leq \hat{P}_{\alpha,r}(X^{-1}((-\infty; x]))\}. \quad (20)$$

The fuzzy cumulative distribution function is the family of the sets

$$F_X = ((F_X)_\alpha)_{\alpha \in (0;1]}. \quad (21)$$

For the family F_X , a fuzzy set $\hat{s} = (\hat{s}_\alpha)_{\alpha \in (0,1]}$ can be defined, such that for each $\alpha \in (0,1]$ and for the parameters $s \in \hat{s}_\alpha$ a unique cumulative distribution function F_s can be found. The fp-r variable F_X is formulated by a bunch parameter representation

$$F_X = (\{F_s \mid s \in \hat{s}_\alpha\})_{\alpha \in (0,1]}, \quad (22)$$

(see also Möller and Beer 2004). In Fig. 4 a visualization of a fuzzy cumulative distribution function and the modeled uncertainty characteristics are shown.

Exemplary Normal Distributed fp-r Variable

An example for a fp-r variable is the normal distributed variable X^{fp-r} , with fuzzy triangular-shaped (Eq. 8) bunch parameters,

$$X^{fp-r} \sim NV(\mu_x^f = \langle 10, 12, 13 \rangle \sigma_x^f = \langle 1.2, 1.3, 1.4 \rangle). \quad (23)$$

In Fig. 5 all possible probability density functions are shown as grayed area.

Robust Design Optimization for Earthquake Loads, Fig. 5 Example of the fuzzy probability-based random density function

Uncertain Structural Analysis

Fuzzy Analysis

Mathematical Formulation

Fuzzy analysis (FA) is the mapping of fuzzy input variables to a fuzzy output variable

$$f^{FA} : \mathcal{F}(A) \rightarrow \mathcal{F}(B) \quad (24)$$

with

$$A \subseteq \mathbb{R}^n \text{ and } B \subseteq \mathbb{R}. \quad (25)$$

A possibility to apply the mapping f^{FA} is the application of the extension principle (Zadeh 1975; Yager 1986):

on the basis of a deterministic analysis

$$f : X \subset \mathbb{R}^n \rightarrow \mathbb{R} : \underline{x} \mapsto z. \quad (27)$$

The computation of $\hat{x}(a)$ needs to consider Eq. 4. The extension principle is accompanied by a high numerical effort, which is not feasible for practical applications. Therefore, an approximate numerical algorithm, called α -level optimization, was adopted in Möller and Beer (2004).

$$\tilde{\underline{x}} \mapsto \left(z \mapsto \sup_{\underline{a} \in f^{-1}(\{z\})} \tilde{\underline{x}}(\underline{a}) \right), \quad (26)$$

Robust Design Optimization for Earthquake Loads, Fig. 6 Sketch of fuzzy analysis based on α -level optimization

α -Level Optimization

The aim of the α -level optimization is the computation of the membership function of the fuzzy result value $\tilde{z}$. Therefore, the min-max operator of the extension principle (Eq. 26) is replaced by optimization tasks. The necessary discretization of the fuzzy input quantities into α -level is defined in Eq. 5. The main idea of this approach is that the necessary information is the minimum and maximum value for the response only, which can be reached at each α -level $\alpha_k \in (0,1]$. The membership values of the result are

$$\alpha_k = \mu(z_{\min, \alpha_k}) = \mu(z_{\max, \alpha_k}). \quad (28)$$

The elements $z | \mu(z_{\min, \alpha_k}) < z < \mu(z_{\max, \alpha_k})$ have no relevance. The task is the computation of the minimum and maximum result value at each α -level; it can be formulated by two optimization tasks

$$\begin{aligned} z_{\min, \alpha_k} &= f(x_1, \dots, x_n) \\ &\rightarrow \min | (x_1, \dots, x_n) \in X_{\alpha_k} \end{aligned} \quad (29)$$

$$\begin{aligned} z_{\max, \alpha_k} &= f(x_1, \dots, x_n) \\ &\rightarrow \max | (x_1, \dots, x_n) \in X_{\alpha_k} \end{aligned} \quad (30)$$

X_{α_k} is the crisp subset (at α -level α_k) of the Cartesian product of the input quantities and

represents the constraints of the optimization problem. In Fig. 6 the procedure is visualized for two input quantities ($n = 2$) and one output quantity. An efficient optimization algorithm is the modified evolutionary optimization algorithm, introduced in Möller et al. (2000).

Stochastic Analysis

An established method to perform an analysis with stochastic quantities is the well-known Monte Carlo simulation (MCS) method. MCS enables a simple method to compute high-dimensional integrals or statistical moments. An engineering-relevant example is the computation of the probability of failure:

$$P_f = \int_{-\infty}^{\infty} I(g(\underline{x})) \cdot f(\underline{x}) d\underline{x}. \quad (31)$$

The input quantities $\underline{x} \in \mathbb{R}^n$ are characterized by the PDFs $f(\underline{x})$.

The indicator function $I(g(\underline{x}))$ is of binary manner and defines failure or not, in dependency of the limit state functions: $\underline{g}(\underline{x})$

$$I(g(\underline{x})) = \begin{cases} 1 & \text{if } g(\underline{x}) \leq 0 \text{ (failure)} \\ 0 & \text{if } g(\underline{x}) > 0 \text{ (no failure)} \end{cases}. \quad (32)$$

Robust Design Optimization for Earthquake Loads, Fig. 7 Data workflow in uncertain analysis with fp-r quantities

The idea of the MCS is the approximate solution of the integral by analyzing different variants/combinations of input quantities, called samples. Yielding the approximate probability of failure

$$\hat{P}_f = \frac{1}{N} \sum_{i=1}^N I(g(x_i)). \quad (33)$$

The sample size is N and the samples x are considered according to the inverse transformation of random quantities:

$$x_i = F^{-1}(u_i). \quad (34)$$

F^{-1} is the inverse function of the CDF (Eq. 16), and $u_i \in [0,1]$ are arbitrary generated, union-distributed random numbers.

Other information of interest, as empirical mean value m_z and empirical variance s_z , can be computed:

$$m_z = \frac{1}{N} \sum_{i=1}^N z_i \quad (35)$$

$$s_z = \sqrt{\frac{1}{N-1} \sum_{i=1}^N (z_i - m_z)^2}. \quad (36)$$

In this method, samples according their PDFs are generated and simulations are computed; the

resulting set of samples yields to an empirical CDF, which is analyzed for P_f , m_z , s_z , or quantile values. This step can be interpreted as information reduction.

Uncertain Analysis with Fuzzy Probability-Based Random Quantities

The application of polymorphic uncertainty models needs specific sequential numerical algorithms for considering fuzzy probability-based random variables. To apply the approach, the fp-r variables need to be defined by the bunch parameters $\underline{s}$ (Eq. 22). The basic uncertainty models and the other polymorphic uncertainty models are included as special cases.

In general, the algorithm can be separated into fuzzy analysis and stochastic analysis. The fuzzy analysis handles the fuzzy properties of the considered uncertainty model; see section “[Fuzzy Analysis](#).” The stochastic analysis takes the uncertainty characteristic variability into account. It is evaluated by standard or advanced MCS; see section “[Stochastic Analysis](#).” In Fig. 7 the sequential reduction of uncertainty is shown. The application of the fuzzy analysis evaluates the incompleteness characteristic by α -level optimization. The variability of the resulting random variable is evaluated by MCS. The deterministic structural analysis (e.g., FEA) computes for the input values $\underline{x}$ and the output quantities $\underline{z}$. The stochastic analysis results in empirical

distribution functions. These distribution functions need to be evaluated and reduced to a deterministic value, e.g., probability of failure P_f , empirical mean values m_z , or empirical variances s_z . By means of the fuzzy analysis, the membership function of these values can be computed. Summarizing, the sequential reduction of uncertainty allows the usage of basic numerical methods for the analysis considering fp-r and lower-level uncertain quantities. The result of an uncertain analysis with fp-r input quantities is a fuzzy quantity for empirical moments of the stochastic analysis.

Earthquake Analysis Under Consideration of Uncertain Data

Algorithmic Formulation

Under consideration of uncertain data, a deterministic function $f : \mathbb{R}^n \rightarrow \mathbb{R} : \underline{x} \mapsto f(\underline{x})$ becomes

$$f^u : \mathcal{D}(Q, R) \rightarrow \mathcal{D}(V, W) : \underline{p}^u \mapsto f^u(\underline{p}^u). \quad (37)$$

The set of uncertain input parameters is abbreviated by $\mathcal{D}(Q, R)$, neglecting further properties. For example, $\mathcal{D}(\mathbb{R}, [0, 1])$ is a set of fuzzy numbers. The variable $\underline{p}^u \in \mathcal{D}(Q, R)$ contains all uncertain parameters. The uncertainty of parameters can be observed for actions and resistance. This means that, e.g., dead loads, earthquake accelerations, or material parameters cannot be described by a deterministic value.

If the uncertain function depends on parameters $\underline{t} = \{\tau, \underline{\theta}, \underline{\varphi}\}$ as time $\tau \in \mathbb{R}^+$, spatial coordinates $\underline{\theta} \in \mathbb{R}^3$, and other parameters $\underline{\varphi} \in \mathbb{R}^{n_{op}}$ with $\underline{t} \in \mathbb{R}^{n_p}$, it yields

$$\begin{aligned} \hat{f}^u : \mathbb{R}^{n_p} \times \mathcal{D}(Q, R) &\rightarrow \mathbb{R}^{n_p} \times \mathcal{D}(V, W) \\ : (\underline{t}, \underline{p}^u) &\mapsto \hat{f}^u(\underline{t}, \underline{p}^u), \end{aligned} \quad (38)$$

with the total number of additional parameters n_p . For a numerical implementation, a discretization of the dependent parameters is necessary (see Möller et al. 2009). For time dependency

only, the uncertain function is called uncertain process and Eq. 38 results in

$$\begin{aligned} \hat{f}_\tau^u : \mathbb{R} \times \mathcal{D}(Q, R) &\rightarrow \mathbb{R} \times \mathcal{D}(V, W) \\ : (\tau, \underline{p}^u) &\mapsto \hat{f}^u(\tau, \underline{p}^u). \end{aligned} \quad (39)$$

For a nonlinear earthquake analysis (time-history analysis), the general equation of motion in the incremental form

$$\underline{M}\Delta\ddot{\underline{v}}(\tau) + \underline{D}\Delta\dot{\underline{v}}(\tau) + \underline{K}_T\Delta\underline{v}(\tau) = \Delta\underline{R}(\tau) \quad (40)$$

is to be solved. The displacement, velocity, and acceleration are described by $\underline{v}(\tau)$, $\dot{\underline{v}}(\tau)$, and $\ddot{\underline{v}}(\tau)$, respectively. The matrix $\underline{M}$ contains the nodal masses and the matrix $\underline{D}$ the nodal damping. The tangential stiffness of the current time step is the content of the matrix $\underline{K}_T$. The external nodal loads are composed in the load vector $\underline{r}(\tau)$. For earthquake loads, that means extrinsic accelerations of the foundation parts of a structure, the displacements can be separated into rigid body displacements $\underline{v}_{\text{rig}}$ and an according relative displacement $\underline{v}_{\text{rel}}$,

$$\underline{v}(\tau) = \underline{v}_{\text{rig}}(\tau) + \underline{v}_{\text{rel}}(\tau). \quad (41)$$

Yielding the modified equation of motion

$$\begin{aligned} \underline{M}\Delta(\ddot{\underline{v}}_{\text{rig}}(\tau) + \ddot{\underline{v}}_{\text{rel}}(\tau)) + \underline{D}\Delta(\dot{\underline{v}}_{\text{rig}}(\tau) + \dot{\underline{v}}_{\text{rel}}(\tau)) \\ + \underline{K}_T\Delta(\underline{v}_{\text{rig}}(\tau) + \underline{v}_{\text{rel}}(\tau)) = \Delta\underline{R}(\tau). \end{aligned} \quad (42)$$

Under consideration of the independence of internal forces and rigid body displacements and the independence of material damping and rigid body velocities, it yields

$$\begin{aligned} \underline{M}\Delta(\ddot{\underline{v}}_{\text{rig}}(\tau) + \ddot{\underline{v}}_{\text{rel}}(\tau)) + \underline{D}\Delta(\dot{\underline{v}}_{\text{rel}}(\tau)) \\ + \underline{K}_T\Delta(\underline{v}_{\text{rel}}(\tau)) = \Delta\underline{R}(\tau). \end{aligned} \quad (43)$$

If the earthquake acceleration is the only load to be considered ($\Delta\underline{R}(\tau)$), the equation of motion, which is to be solved, can be simplified as

$$\begin{aligned} \underline{M}\Delta(\ddot{\underline{v}}_{\text{rel}}(\tau)) + \underline{D}\Delta(\dot{\underline{v}}_{\text{rel}}(\tau)) + \underline{K}_T\Delta(\underline{v}_{\text{rel}}(\tau)) \\ = \underline{M}\Delta(\ddot{\underline{v}}_{\text{rig}}(\tau)) \end{aligned} \quad (44)$$

The inertial displacements of the accelerated soil $\underline{v}_{\text{soil}}(\tau)$ can be considered with

$$\underline{v}_{\text{rig}}(\tau) = \underline{Z} \cdot \underline{v}_{\text{soil}}(\tau), \quad (45)$$

by defining an allocation vector $\underline{Z}$. The solution gives the time-dependent structural response. For a numerical applicability, the necessary discretization into time steps $\tau_i = \tau_{i-1} + \Delta\tau i \in \{1, 2, \dots, n_t\}$ yields

$$\begin{aligned} f_{\tau=\tau_i}^u : \mathcal{D}(Q, R) &\rightarrow \mathcal{D}(V, W) \\ : \underline{p}^u &\mapsto \hat{f}_{\tau}^u(\tau_i, \underline{p}^u). \end{aligned} \quad (46)$$

This discretization is realized by implicit and explicit time integration methods in the framework of FEA.

It has to be remarked that the formulations shown in the following, for the consideration of time dependency, are only valid if the uncertain structural parameters are not time dependent.

Numerical Variants for the Analysis of Uncertain Dynamical Processes

The consideration of polymorphic uncertain variables, e.g., fp-r variables, in a numerical procedure, can be accomplished by a sequential reduction of the level of uncertainty; see section “Uncertain Analysis with Fuzzy Probability-Based Random Quantities.”

The time dependency of additional parameters can be considered by two different approaches. On the one hand, there is variant I, which needs to compute the uncertain analysis for each time step $\tau_i \in \tau$. The result is an uncertain process of the response variable. This concept is highly time-consuming. The structure of the algorithm for fp-r variables is shown in Fig. 8.

On the other hand, in variant II the dynamical process is computed in the inner sequence. This concept is less time-consuming, due to the necessary reduction of information for the deterministic dynamical process. This means that the response process has to be reduced to a deterministic value, e.g., average or maximal value. The result is one uncertain response value, according to the selected information reducing measure. The algorithm is sketched in Fig. 9.

Robust Design Optimization for Earthquake Loads, Fig. 8 Variant I for uncertain dynamical processes

Robust Design Optimization for Earthquake Loads, Fig. 9 Variant II for uncertain dynamical processes

Increasing Numerical Efficiency

The applicability of polymorphic uncertainty models for earthquake analysis is, due to the enormous numerical effort, limited. The consideration of polymorphic uncertainty models makes it necessary to reduce the computational effort. There are three essential possibilities:

- Reduction of calculation time for the deterministic analysis or reduction of necessary number of evaluations of the deterministic solutions
- Replacement of the deterministic solution with efficient metamodels
- Parallel evaluation of deterministic simulations

The reduction of the necessary number of evaluations of the deterministic analysis is possible for polymorphic uncertainty models, due to

the sequential evaluation of fuzzy and stochastic properties; see section “[Uncertain Structural Analysis](#),” for these two sequences. The stochastic solution can be applied by standard MCS or by more efficient technologies as subset sampling. The solution for fuzzy quantities can be improved by applying efficient optimization technologies for the α -level optimization or a specific evaluation of needed points of the membership function.

Both have in common that the numerical effort increases with growing numbers of uncertain parameters. This means that reducing the number of uncertain quantities improves the numerical efficiency. This necessary categorization of uncertain quantities into relevant and nonrelevant is possible by analyzing the sensitivity for each input quantity according to the output quantity of interest (see, e.g., Saltelli et al. 2008). Metamodels are versatile, e.g., they are applicable for pattern classification, function approximation, or computing sensitivity measures. The possibility to approximate functional data, a mapping of input quantities to output quantities

$$f^* : \mathbb{R}^n \supset H^n \rightarrow \mathbb{R}^m \quad (47)$$

can be done by several types of metamodels (see Søndergaard 2003). The definition of the region of interest $H^n = [a_1; b_1] \times \cdots \times [a_n; b_n] | a_i, b_i \in \mathbb{R}, a_i \leq b_i, i \in \{1, \dots, n\}$ is necessary to avoid extrapolating. The metamodel f^* can be found on the basis of a set of support points $\mathcal{N} = \{(\underline{x}, \underline{z}) | \underline{x} \in H^n, \underline{z} \in H^m\}$, which provide the relations between input and output quantities of the original function $f : \mathbb{R}^n \rightarrow \mathbb{R}^m, \underline{x} \mapsto \underline{z}$ pointwise. There are well-established metamodels to approximate functional data, as artificial neural networks (ANN) or radial basis function networks (RBFN).

Robustness

Robustness Measure

Several interpretations of robustness are known and introduced. Robustness can be the resistance against extraordinary events, the limited variations of structural response and redundancy,

prevention of progressive failure in the case of local failure, and the ratio of direct risks to indirect risks. A main contribution in the field of designing robust structures is developed by Beer and Liebscher (2008). The interpretation of robustness in this contribution is the sophisticated ratio of uncertainty of input quantities $\underline{x}^u$ to the uncertainty of result quantities $\underline{z}^u$. The robustness measure R was introduced in Graf et al. (2010) and Sickert et al. (2010):

$$R = \frac{\sum_{i=1}^l k_i \cdot P_i(\mathcal{U}(x_i^u)) + \sum_{k=l+1}^n k_k \cdot P_k(\mathcal{U}(x_k^u))}{\sum_{i=1}^l k_i \cdot \left(\sum_{j=1}^m k_{i,j} \cdot P_{i,j}(\mathcal{U}(z_{i,j}^u)) \right)}. \quad (48)$$

The robustness measure for a structure is analyzed considering the uncertain quantities with n uncertain input parameters x_w^u . In contrast, l load and failure scenarios, represented by the uncertain load input variables, are considered separately. There are m uncertain result variables z_w^u , which have to be taken into account. All uncertain variables $y^u \in \{x_w^u, z_w^u\}$ have in common that the measures describing the uncertainty

$$\mathcal{U} : \mathcal{D}(Q, R) \rightarrow \mathbb{R} : y^u \mapsto \mathcal{U}(y^u) \quad (49)$$

have to be found; selected measures are described in section “[Information Reducing Measures for Uncertain Quantities](#).” The measures need to be selected for the related uncertainty model and a deliberated selection has to provide the comparability of the measures. The penalty functions $P_w(\cdot)$ and the weighting factors k_w are necessary to enable the possibility of a problem-dependent adaption of the robustness measure. The proposed robustness measure is relative and does not represent an absolute value about the robustness of structures. The main benefit is the independence from the used uncertainty model.

Information Reducing Measures for Uncertain Quantities

Information reducing measures $\mathcal{M}$ map uncertain quantities to deterministic values:

$$\mathcal{M} : \mathcal{D}(Q, R) \rightarrow \mathbb{R}. \quad (50)$$

In general, the measures for uncertain quantities can be classified into representative values $\mathfrak{M}$ and values to quantify the amount of uncertainty $\mathfrak{U}$. For fuzzy quantities, the reduction of information is called defuzzification. This contribution shows information reducing measures for random and fuzzy variables. To avoid confusion, random variables $Y \in \mathcal{D}(\Omega, \mathbb{R})$ are defined by the CDF $V_y: \mathbb{R} \rightarrow [0; 1]$ and the PDF $v_y: \mathbb{R} \rightarrow [0; \infty)$. A fuzzy variable $\tilde{y} \in \mathcal{F}(\mathbb{R})$ is given by the membership function $\mu_{\tilde{y}}: \mathbb{R} \rightarrow [0; 1]$ and by the family of α -level cuts, according to Eq. 6.

Representative Measures

For random variables, the representative measures

- Mean value

$$\mathfrak{M}_E^r(Y) = \int_{-\infty}^{\infty} y \cdot v_Y(y) dy \quad (51)$$

- Quantile value

$$\mathfrak{M}_Q^r(Y) = V_Y^{-1}(q) | q \in (0, 1) \quad (52)$$

can be found. For fuzzy variables, the representative measures mean value, level rank method, and extremal values can be found. The mean value, also centroid method, is equal to the centroid of the area of the membership function. The level rank method represents the mean of the center point of each α -level (see Rommelfanger 1988). The extremal values can be used for “worst-case” observations.

- Mean value

$$\mathfrak{M}_E^f(\tilde{y}) = \frac{1}{\mathfrak{U}_A^f(\tilde{y})} \int_{-\infty}^{\infty} y \cdot \mu_{\tilde{y}}(y) dy \quad (53)$$

- Level rank method

$$\mathfrak{M}_L^f(\tilde{y}) = \frac{1}{i} \sum_{k=1}^i \frac{\tilde{y}_{\alpha_{k,l}} + \tilde{y}_{\alpha_{k,r}}}{2} \quad (54)$$

- Minimum

$$\mathfrak{M}_{\text{Min}}^f(\tilde{y}) = \tilde{y}_{\alpha_{0,l}} \quad (55)$$

- Maximum

$$\mathfrak{M}_{\text{Max}}^f(\tilde{y}) = \tilde{y}_{\alpha_{0,r}} \quad (56)$$

Uncertainty Measures

The measures describing the uncertainty for random quantities are

- Variance

$$\mathfrak{U}_V^r(Y) = \int_{-\infty}^{\infty} v_y(y) \cdot (y - \mathfrak{M}_E^r(Y))^2 dy \quad (57)$$

- Entropy

$$\mathfrak{U}_E^r(Y) = \int_{-\infty}^{\infty} v_y(y) \cdot \ln(v_y(y)) dy \quad (58)$$

The uncertainty measures for fuzzy variables are

- Area

$$\mathfrak{U}_A^f(\tilde{y}) = \int_{-\infty}^{\infty} \mu_{\tilde{y}}(y) dy \quad (59)$$

- Variance

$$\mathfrak{U}_V^f(\tilde{y}) = \frac{1}{\mathfrak{U}_A^f(\tilde{y})} \int_{-\infty}^{\infty} \mu_{\tilde{y}}(y) \cdot (y - \mathfrak{M}_E^f(\tilde{y}))^2 dy \quad (60)$$

- Entropy

$$\mathfrak{U}_E^f(\tilde{y}) = -\frac{1}{\ln(2)} \int_{-\infty}^{\infty} \mu_{\tilde{y}}(y) \cdot \ln(\mu_{\tilde{y}}(y)) + (1 - \mu_{\tilde{y}}(y)) \cdot \ln(1 - \mu_{\tilde{y}}(y)) dy \quad (61)$$

Representative and uncertainty measures of fp-r variables can be found in Pannier (2011).

Numerical Design of Processes with Uncertain Parameters

The numerical design of a process can be accomplished by different procedures. The easiest way is to analyze different variants; other procedures are optimization or the solution of the inverse problem. The aim of the design can be described by an objective function for, e.g., efficiency, profitability, reliability, robustness, or sustainability. These goals can be formulated as various constraints or objective functions.

The method, proposed in this contribution, is an optimization approach for parameterized optimization problems. The idea is to find a combination of various uncertain parameters yielding the best uncertain response, whereas the best design is related to the highest robustness.

Uncertain Optimization Task and Split of Uncertain Variables

The optimization objective function under consideration of uncertain quantities is written as

$$\hat{f}_Z^u : \mathcal{D}(Q, R) \rightarrow \mathcal{D}(V, W). \quad (62)$$

The uncertain input quantities $\mathcal{D}(Q, R)$ can be classified into uncertain design variables $\underline{x}_d^u \in \mathcal{D}(Q_x, R_x)$ and uncertain a priori parameters $\underline{p}^u \in \mathcal{D}(Q_p, R_p)$, holding

$$\mathcal{D}(Q_x, R_x) \times \mathcal{D}(Q_p, R_p) = \mathcal{D}(Q, R). \quad (63)$$

The value of a priori parameter is independent of the current design. But, an optimization algorithm for the direct consideration of polymorphic uncertain design variables does not exist. This means that the application of uncertain design variables is not possible, directly. A solution is the application of an affine transformation $\mathcal{T}$ to the uncertain design variables. This transformation splits them to deterministic design variables $\underline{d} \in \mathbb{R}^{n_x}$ (suitable for optimization algorithms) and further (constant) uncertain a priori variables, containing the set $\underline{p}^u$. The affine transformation has to be defined for each uncertainty model.

Random Variables

$$\begin{aligned} \mathcal{T}^r : \mathbb{R}^{n_x} &\rightarrow \mathcal{D}(\Omega, \mathbb{R}^{n_x}) \\ : \underline{d} &\mapsto (\underline{\omega} \mapsto c(\underline{d}) \cdot U(\underline{\omega}) + \underline{d}) \\ &= \underline{X}_d | U \in \mathcal{D}(\Omega, \mathbb{R}^{n_x}) \end{aligned} \quad (64)$$

Fuzzy Variables

$$\begin{aligned} \mathcal{T}^f : \mathbb{R}^{n_x} &\rightarrow \mathcal{F}(\mathbb{R}^{n_x}) \\ : \underline{d} &\mapsto (c(\underline{d}) \cdot \underline{u} + \underline{d} \mapsto \tilde{u}(\underline{u})) \\ &= \tilde{\underline{X}}_d \quad | \tilde{\underline{X}}_d \in \mathcal{F}(\mathbb{R}^{n_x}) = \mathcal{D}(\mathbb{R}^{n_x}, [0, 1]) \end{aligned} \quad (65)$$

Fuzzy Probability-Based Random Variables

$$\mathcal{T}^{fp-r} = \mathcal{T}^r \text{ (due to not involved probability measure)} \quad (66)$$

The application of the affine transformation yields to the objective function (Eq. 62)

$$\begin{aligned} f_Z^u : \mathbb{R}^{n_x} \times \mathcal{D}(Q_p, R_p) &\rightarrow \mathcal{D}(V, W) \\ : (\underline{d}, \underline{p}^u) &\mapsto \hat{f}_Z^u(\mathcal{T}(\underline{d}), \underline{p}^u). \end{aligned} \quad (67)$$

The “uncertain” optimization task can be formulated as

$$\begin{aligned} &\text{determine } L \subseteq X_d^+ \text{ such that } \forall \underline{d} \in X_d^+ \text{ and } \underline{d}_{min} \in L \text{ it holds :} \\ &f_Z^u(\underline{d}_{min}, \underline{p}^u) \text{ is “lower or equal than” } f_Z^u(\underline{d}, \underline{p}^u). \end{aligned}$$

The objective is to find

$$\underset{\underline{d} \in X_d^+}{\text{minimum}} f_Z^u(\underline{d}, \underline{p}^u), \quad (68)$$

under consideration of the uncertain permissible range

$$\begin{aligned} X_d^+ &= \{\underline{d} \in \mathbb{R}^{n_x} | \forall j \in \{1; \dots; a_g\} : \\ g_j^u(\underline{d}, \underline{p}^u) \text{ “lower than” } 0 \\ \wedge \forall k \in \{1; \dots; a_h\} : h_k^u(\underline{d}, \underline{p}^u) \text{ “equal” } 0\} \end{aligned}, \quad (69)$$

with the uncertain constraints

$$\begin{aligned} g_j^u : \mathcal{D}(Q, R) &\rightarrow \mathcal{D}(V, W) \text{ and } h_k^u \\ : \mathcal{D}(Q, R) &\rightarrow \mathcal{D}(V, W). \end{aligned} \quad (70)$$

Due to the missing of a general rule for comparing uncertain quantities, relational operators as $<$, $>$, and $=$, used in the introduced design task and the related constraints and the usually used minimum operator “min” for a deterministic case in Eq. 68, are not applicable. This means the solution of the design task with uncertain quantities can be found for surrogate problems only. The surrogate problem can be formulated as passive or active approach (see Pannier 2011; Götz et al. 2013). Both approaches mainly differ in the order of evaluation of uncertainty task and solving the optimization problem. This contribution shows an algorithm for computing a robust design by an application of the active approach.

Numerical Optimization Algorithm for Consideration of Uncertain Quantities

The active approach is also denoted as *here-and-now* strategy (Tintner 1960). The generalized formulation for polymorphic uncertain quantities is

$$\begin{aligned} &\text{determine } L \subseteq X_d^+ \text{ such that} \\ &\forall \underline{d} \in x_d^+ \text{ and } \underline{d}_{min} \in L \text{ it holds :} \\ &\mathcal{M}\left(f_z^u(\underline{d}_{min}, p^u)\right) \leq \mathcal{M}\left(f_z^u(\underline{d}, p^u)\right). \end{aligned}$$

Selected deterministic design quantities d (Fig. 10, ①) were transformed to uncertain design quantities x_d^u and the uncertain result quantities (Fig. 10, ②) can be computed. The application of information reducing measures

$$\mathcal{M} : \mathcal{D}(V, W) \rightarrow \mathbb{R} \quad (71)$$

allows the reduction to deterministic values and further optimization processing; see section “Information Reducing Measures for Uncertain Quantities.” The numerical algorithm, for the design of an uncertain process type variant II (Fig. 9), is shown in Fig. 11.

There are seven major steps:

1. The preprocessing provides the objective function, with deterministic input variables, according to Eq. 67. The actual deterministic design variables and the uncertain a

Robust Design Optimization for Earthquake Loads, Fig. 10 Optimization procedure for uncertain objective functions

priori parameter are combined by applying the affine transformation.

2. The uncertainty analysis for processes, with the sequential reduction of uncertainty, computes the uncertain result; see section “Numerical Variants for the Analysis of Uncertain Dynamical Processes.” For variant II it results in an uncertain response, representing the main characteristics of the uncertain process.
3. The structural dynamic objective function is the core of this design algorithm; it provides the deterministic relations between deterministic inputs and deterministic (time-dependent) outputs. This part could be applied by an FEA, but numerical efforts should be reduced by the application of metamodels; see section “Increasing Numerical Efficiency.”
4. The optimization objective function checks constraints (maybe further uncertain analysis is necessary), Eq. 70. For the application of variant I, it is necessary to reduce the uncertain response process to a representative uncertain value.
5. The postprocessing has the main focus of this contribution; it computes the robustness of the current design (see section “Robustness Measure”), taking the uncertainty of the current design and the uncertainty of the response variables into account. It provides a deterministic value, representing the quality of the current design. For other objectives of optimization, only the application of information reducing measures is necessary.

Robust Design Optimization for Earthquake Loads, Fig. 11 Algorithm for the design of processes under consideration of fp-r variables

- 6. The deterministic optimization algorithm updates the deterministic design variables.
- 7. The result is a deterministic design yielding to a robust structure, under consideration of dynamical structural behavior and uncertainty of data and information.

This approach is the basis for reliability-based optimization (RBO) methods (see, e.g., Enevoldsen and Sørensen 1994).

Example

Model Description

In this example, an existing RC structure, Fig. 12, should be strengthened for earthquake loading (Sickert et al. 2011). Previous studies (e.g., Steinigen et al. 2012) found that the RC frame has two independent mode shapes for longitudinal and lateral directions. The point of view in this example is the behavior in lateral direction. The RC frame should be coupled with a steel frame, and the objective of the optimization is to find optimal parameters of the connecting device, yielding a robust design, under consideration of an uncertain action process, with respect to the introduced variant II.

In Table 1 the uncertain input parameters of the structure are given. Due to the missing of any information about loading and material, the input parameters are modeled as triangular-shaped fuzzy variables (Eq. 8). The lateral structure is modeled as nonlinear 2DOF system; see Fig. 13. With the help of a fuzzy pushover analysis,

Robust Design Optimization for Earthquake Loads, Fig. 12 RC frame structure

Robust Design Optimization for Earthquake Loads, Table 1 Input data of the uncertain process for the 2DOF system

Fuzzy parameter	Value
$\tilde{\gamma}$ [mm/kN]	$\langle -3.3, 0.0, 6.0 \rangle \cdot 10^{-3}$
$\tilde{d}(F)$ [mm]	$d(F) + \tilde{\gamma} \cdot F$
$\tilde{K}_2$ [kN/m]	$\langle 50, 52.5, 55 \rangle \cdot 10^3$
$\tilde{M}_2$ [t]	$\langle 1.2, 1.5, 1.8 \rangle$
$\tilde{a}_I(\tau)$ [m/s ²]	$\frac{a_I(\tau)}{2.5} \cdot \langle 2, 2.25, 2.5 \rangle$
$\tilde{c}_{x,p}$ [kNs/m]	$\langle 0.9, 1.0, 1.1 \rangle$
$\tilde{k}_{x,p}$ [kN/m]	$\langle 0.0, 100.0, 150.0 \rangle$

Robust Design Optimization for Earthquake Loads,
Fig. 13 2DOF simulation model of the strengthened RC structure in lateral direction

Fig. 14, the uncertain nonlinear behavior of the RC frame could be included in the simulation model. This nonlinear force-displacement kernel curve is scaled by the parameter $\tilde{\gamma}$. The stiffness and mass of the steel frame are modeled by $\tilde{K}_2$ and $\tilde{M}_2$, respectively.

The load cases of the structure are ground motions; three acceleration-time dependencies of measured earthquakes are regarded: the acceleration-time dependencies $a_I(\tau)$ measured during the earthquakes in El Centro 1940, Calitri 1980, and Taiwan 1999, for instance (see Fig. 15). The acceleration-time dependencies are scaled to a peak ground acceleration (PGA) value of 0.25 g, applied to the 2DOF system. For a realistic modeling of earthquake loads, it is necessary to consider the uncertainty of the measured accelerations; therefore, the scaling with a fuzzy value yields $\tilde{a}_I(t)$.

Uncertain Analysis

Due to the application of the variant II to analyze uncertain processes, a realization of the uncertain parameters is determined in the first sequence. The solution of the dynamic structural analysis, in this case the solution of the equation of motion, Eq. 40, is found in the inner sequence. The time-displacement dependencies are computed for the 2DOF system. Realizations of the time-displacement functions during the Taiwan earthquake of both parts of the systems can be seen in

Fig. 16. The maximum displacements of the RC structure, during each earthquake acceleration, $\underline{v}_{MD,i} = \max v_1(\tau) \mid i \in \{1, 2, 3\}$, is the result of the postprocessing procedure. The result of the uncertain analysis is the fuzzy maximum displacements $\tilde{v}_{MD,i} \mid i \in \{1, 2, 3\}$.

Robust Design of Connection Device

Design Objectives

The design parameters are the viscosity c_x and stiffness k_x of the damping device:

$$\tilde{c}_x = c_{x,d} \cdot \tilde{c}_{x,p} \quad \text{and} \quad (72)$$

$$\tilde{k}_x = k_{x,d} \cdot \tilde{k}_{x,p}. \quad (73)$$

The split of uncertain a priori and deterministic design part is applied. The uncertain a priori parameters $\tilde{c}_{x,p}$ and $\tilde{k}_{x,p}$ are shown in Table 1. The design ranges of the parameters are

$$c_{x,d} \in [0, 10000] \text{ kN/m and} \quad (74)$$

$$k_{x,d} \in [0, 10000] \text{ kNs/m.} \quad (75)$$

The general optimization task is to “compute optimal connection device parameters for a robust structure.” Therefore, the robustness measure, Eq. 48, is evaluated for the three load cases. The uncertainty is assessed by applying the information reducing measure entropy for fuzzy quantities (Eq. 61). The weighting factors and penalty functions of the robustness measure are here not considered. For the design d , it yields

$$R_d = \frac{\sum_{i=1}^{l=3} \left(\mathcal{U}_E^f(\tilde{c}_{x,d,i}) + \mathcal{U}_E^f(\tilde{k}_{x,d,i}) \right)}{\sum_{i=1}^3 \mathcal{U}_E^f(\tilde{v}_{MD,d,i})} \quad (76)$$

$$= \frac{3 \cdot (0.1453346 \cdot c_{x,d} + 109.001)}{\sum_{i=1}^{l=3} \mathcal{U}_E^f(\tilde{v}_{MD,d,i})}. \quad (77)$$

Robust Design Optimization for Earthquake Loads, Fig. 17 Result of the uncertain design of processes

Results

In Fig. 17 the result of the robust design analysis is shown. In the shown part of the design space $c_{x,d} \in [5,500, 6,000]$ kN/m and $k_{x,d} = 0.0$ kNs/m, the summed result of the earthquake analysis $\sum v_{MD}$ is set on the left axis and the related robustness R_d is set on the right axis. The blue dotted line shows the summed displacement at $\alpha = 1$. The fuzzy result $\sum v_{MD}$ is shown for the two examples. The robustness for the observed designs is shown with green dots (scaled to $\max(R) = 1.0$). The optimal robust design is found for the parameters $c_{x,d} = 5,894$ kN/m and $k_{x,d} = 0.0$ kNs/m taking uncertainty into account. This means,

$$\begin{aligned} \tilde{c}_x &= \langle 5304.6, 5894.0, 6483.4 \rangle \text{ kN/m and} \\ \hat{k}_x &= \langle 0.0, 100.0, 150.0 \rangle \text{ kN/m} \end{aligned} \quad (78)$$

were considered.

Summary

In this contribution, parameterized robust design of structures under earthquake loads is shown. The necessary capturing of uncertainty is done by using fuzzy, random, and fuzzy probability-based random variables. The numerical algorithms are shown in detail, with the focus of

reusing existing uncertainty analysis methods and available optimization approaches. Robustness of a structure is defined as the ratio of the amount of uncertain input quantities to the amount of uncertain output quantities. The example shows the applicability of robust design optimization for earthquake loads.

Rockfall Seismicity Accompanying Dome-Building Eruptions

Nick Varley

Facultad de Ciencias, Centre of Exchange and Research in Volcanology, Universidad de Colima, Colima, Mexico

Synonyms

Dome collapse; Earthquakes; Effusive eruption; Magma emplacement; Magma extrusion

Introduction

Dome-building eruptions are very common at volcanoes and can present a considerable threat to the nearby population. In this entry they are discussed with reference to the seismicity that is generated by the dome growth process, which often provides an insight into the associated processes. Small earthquakes frequently occur during dome emplacement, and modelling their generation has helped in the understanding of the processes occurring during magma extrusion (e.g., Iverson et al. 2006; Varley et al. 2010). The second type of seismogenic phenomena are dome collapses, which result from the emplacement of magma at the surface and the inherent instability of the resulting dome structure. In this case studying the seismic signals can provide estimates of the characteristics of the resulting rockfall or pyroclastic flow.

Analysis of the seismicity that accompanies dome growth is improving our understanding of

their construction and can aid in the mitigation of associated risks. This entry discusses the formation of lava domes and the associated risk to populations close to the volcano. The seismicity generated by magma ascent is discussed: how rockfalls are generated from domes and what are the characteristics of the resulting seismic signals. A comparison is made with the characteristics of the seismicity produced by other mass movements down slopes, with the utility of these signals highlighted.

Volcanic Domes

Magma erupts in a variety of fashions, mainly determined by its physical properties, the amount of gas contained, and its ability or inability to escape the magma during decompression. Explosive activity varies from relatively weak eruptions, called Strombolian, that form scoria cones, the most common continental volcanic feature, to large dangerous Plinian eruptions, characteristic of tall stratovolcanoes associated with subduction of plates along many boundaries across the globe. Usually the most significant threat comes from the possibility of a large explosive eruption, which may produce pyroclastic flows that can reach many tens of km from the volcano and destroy everything in their path. However, the formation of a dome also has the potential for large-scale destruction.

Viscous lava will accumulate upon extrusion in an eruption forming a lava dome rather than flowing away as is the case for more fluid low-silica magma such as basalt. Stratovolcanoes are usually constructed from intermediate magma, and by nature, the magma erupts either with high volatile contents and fast ascent producing explosive eruptions or more slowly and with low gas contents resulting in dome construction. Domes can be isolated structures, e.g., San Pedro, Nayarit, Mexico (Fig. 1), or in groups such as Lassen Peak in California, or as part of chains such as the Mono Lake-Inyo Craters in California, USA, where four of 13 domes have erupted in the last 600 years (Hildreth 2004). As in the case of Lassen Peak, domes can reach several

hundreds of meters in height. However, the majority of domes represent a distinct episode in the complex story of magma ascent and emplacement and explosions with pyroclastic flows and tephra fall that together construct a stratovolcano.

Domes grow to fill or partially fill summit craters or lower on the flanks for eruptions associated with lateral dykes. Examples of recent summit dome-forming eruptions are those at Volcán de Colima, Mexico (Lavallée et al. 2012; Fig. 2), or Redoubt, USA (Coombs et al. 2013). However, the eruptive history of the volcano might result in growth at a different location on the volcano's flanks, for example, the long-lived dome-building eruption at Santa Maria, Guatemala. The dome complex Santiaguito started growing in 1922 and, after several shifts in the focus of extrusion, continues to produce magma today within the scar left by the 1902 eruption, located below the summit (Rose 1972; Fig. 3). This dome complex is an example of where cyclicity can be observed with variation in the effusion rate over distinct periods of time (Barmin et al. 2002). The period of such cycles can vary from years to just days, such as observed at Soufrière Hills Volcano, Montserrat (Loughlin et al. 2010; Fig. 4). Any foresight regarding the effusion rate for a growing dome would be invaluable for the mitigation of the risks associated with collapse events.

Risks Associated with Dome Growth

Volcanic domes can present a major risk due to the likelihood of collapse. Some of the principal recent volcanic disasters have been associated with this phenomenon, the most notable being the eruption of Mt. Pelee, Martinique, in 1902, during which the city of was wiped out by a pyroclastic flow, killing around 28,000 people. These flows develop when the dome is pressurized; a partial collapse will produce decompression which initiates fragmentation of the magma. The resulting mixture of ash and hot gas, accompanied by large blocks, will descend the volcanic flank at high speed due to gravity.

R

The gas gives the flow mobility, and their runout distance can be many km, much greater than a rockfall event. Pressurization within the dome is determined by the exsolution of volatiles, which in turn is partly controlled by the extrusion rate. At Volcán de Colima, pyroclastic flows were rare and only very small during the very slow dome growth that occurred between 2007 and 2011, whereas the faster effusion rate which was witnessed in 2004 resulted in frequent

pyroclastic flows, the largest reaching 6.1 km from the volcano. As a comparison, rockfalls at this volcano do not reach more than 2 km of distance.

Volcanic domes grow at different rates from extremely slow like the case of Volcán de Colima from 2007 until 2011, which grew at a rate of $0.02 \text{ m}^3 \text{ s}^{-1}$ (Varley et al. 2010) to a fast rate such as the case of Chaitén, Chile, which initially grew at $66 \text{ m}^3 \text{ s}^{-1}$ (Pallister et al. 2013).

to both rockfalls and internal earthquakes); 1 January to 1 July 2006 (Figure provided by Silvio De Angelis)

A faster growth rate implies greater pressurization within the dome, which in turn increases the potential for far-reaching pyroclastic flow and hence far greater risks. Once a dome growing within the summit crater of a stratovolcano has reached the rim, it will begin to overflow in the form of rockfalls and possibly form a lava flow.

Merapi in Indonesia deserves a special mention with its long history of frequent pyroclastic flow generation associated with the growth of a dome on the upper flanks. In 1994 a flow killed over 60 people, and it was thought to have been generated by pure gravitational collapse of the

growing dome, whereas events of 1997 and 1998 were more fluid due to gas pressurization with the lava dome (Voight et al. 2000). The 1994 collapse was estimated at $2.5 \times 10^6 \text{ m}^3$ with the various pyroclastic flows occurring over a period of about 7 h, reaching 6.5 km from the volcano. The event did not coincide with periods of high extrusion rates which had declined over 3 months prior to the collapse (Voight et al. 2000).

A seismic event classification scheme specific to Merapi included “multiphase” events which were detected during rapid dome growth. They are somewhat similar to hybrid events in other

Rockfall Seismicity Accompanying Dome-Building Eruptions, Fig. 5 Seismicity recorded at Merapi, Indonesia, on 15 June–12 August 1998 from rockfall events and multiphase earthquakes, which are associated with

dome growth at Merapi. The indicated eruption on 11 July was a dome collapse (Adapted from Voight et al. 2000)

classification schemes for volcano seismicity. These events occur at a rate of up to several 100 per day, are shallow, have an emergent waveform, and are characterized by frequencies of 3–4 Hz; however, their generation mechanism remains poorly understood. Seismicity recorded from a broadband seismometer was used to analyse dome collapse events during the 1994 eruption, with the assumption that the volume was proportional to the seismic magnitude for a similar source area and descent path (Brodscholl et al. 2000). Figure 5 shows the increase in multiphase-type seismicity associated with a dome collapse in 1998, with 33 events occurring per week in mid-June to 2029 in the 6 days ending 12 July (Voight et al. 2000). The increase in seismicity was accompanied by an increase in

the number of rockfalls (as well as tilt); the correlation indicating that the parameters were related to increasing effusion rates. These pyroclastic flows did not result in casualties since clear precursors were detected allowing evacuations to take place, even though the volume of material was larger than in 1994 at $8.8 \times 10^6 \text{ m}^3$.

The eruption at Soufrière Hills Volcano, Montserrat, has produced many dome collapses which have dominated the hazards presented to the local population. Decompression from the large December 1997 dome collapse produced a large explosion with highly mobile pyroclastic density currents (Woods et al. 2002). These flows have been at times complex with multiple pulses (Loughlin et al. 2002). The role of gas-rich magma batches has been considered as a

Rockfall Seismicity Accompanying Dome-Building Eruptions, Fig. 6 Swarms of LP events at Volcán de Colima related to magma ascent and dome formation in 2005. A poor correlation between the duration of the

seismic swarm and the magnitude of the seismicity associated with the explosion that subsequently occurred destroying any domes forming within the crater

contributing factor in the destabilizing process prior to major collapse events such as in 2006 (De Angelis et al. 2007).

Magma Ascent and Emplacement

Ignoring external factors, such as the interaction with water, it is the magma ascent rate, combined with its viscosity and volatile contents, which determines whether an eruption is explosive or effusive. The more efficiently the magma can release its volatile cargo, the more likely the eruption will result in lava domes or flows, rather than undergo fragmentation with the rapid expansion of gases and the emission of ash in an eruption column.

A particular type of seismicity is often recorded during slow magma ascent. As already discussed, in the case of Merapi, so-called multiphase events can be used to qualitatively

estimate the magma ascent rate (Voight et al. 2000). Many other volcanoes have produced low-frequency seismicity during effusive eruptions, often in form of swarms, where the events are concentrated in time and/or multiplets, when they are also concentrated in space.

Modelling magma ascent in the conduit has highlighted the most important factors, with interactions along the conduit wall dominating, whether it is gas loss through the walls themselves or the transformation from ductile to brittle behaviour due to increased shear; they are critical in determining the final eruptive style. At Volcán de Colima, small-magnitude long-period (LP) events were recorded in swarms lasting from 6 hours to 3 days, prior to moderately large Vulcanian explosions that produced pyroclastic flows reaching up to 5.4 km from the volcano (Varley et al. 2010). As shown in Fig. 6 there was little relation between the duration of the swarm and the size of the associated

Rockfall Seismicity Accompanying Dome-Building Eruptions,

Fig. 7 Small rockfall descending the western flank of Volcán de Colima during period of dome growth (30 April 2013). A cloud of dust has been generated with the impacts of individual rocks visible on the slope

explosion as recorded by the seismicity resulting from the event. The majority of swarms continued for a considerable time after the explosion, with an increase in the magnitude of the LP events. It was suggested that the magnitude was related to the strain rate and thus the ascent velocity of the magma in the conduit, with brittle deformation generating the events (Goto 1999; Neuberg et al. 2006; Varley et al. 2010). There was clear evidence for magma ascent since small domes were also observed at Volcán de Colima emplaced during the height of the explosive activity.

Generation of Rockfalls

Rockfalls can be described as mass movements of material down a slope by gravity, whereby the detachment occurred along discontinuities such as fractures, joints, or bedding planes and the motion is one of free fall, bouncing, and rolling. Bourrier et al. (2013) recognize that a more precise definition is required and propose two end-members being fragmental rockfall (where there is a greater interaction with the slope than between individual particles) and rock mass fall (particles interact with each other and travel as a deforming mass). Clearly for dome-forming volcanic eruptions, the fragmental rockfall would be

more usual. The magnitude of a rockfall can vary from very small, perhaps just a few rocks, to an event producing a column large enough to be mistaken for one generated by an explosion (as was the case at Mt. St. Helens; Moran et al. 2008). Although typically the term “rockfall” is used to describe all collapse events associated with growing lava domes, which lack a dominant gas phase to generate a pyroclastic density current, the term “rockslide” might be applicable in some cases, where initial movement is one of translation rather than free fall.

Rockfalls associated with volcanic activity are most often associated with growing domes or the front of lava flows, the former being of a larger magnitude. Figure 7 shows a relatively small rockfall from the slowly growing dome at Volcán de Colima. The effusion of silicic lava produces blocks which accumulate with low stability. The morphology of these structures is dependent on various factors including: composition, lava temperature, volatile contents, crystal contents, and effusion rate. A steeper front will produce more frequent and greater-magnitude rockfalls. When there is gas pressurization within the dome, a rockfall can easily transform into a pyroclastic density current which has greater mobility due to the high proportion of hot gases in its composition. Small events might have a volume of $<10 \text{ m}^3$, whereas a large dome collapse, such as

the events at Soufrière Hills Volcano, can be up to $>5 \times 10^7 \text{ m}^3$ (Woods et al. 2002).

The relationship between effusion rate and rockfall production is not necessarily simple (Loughlin et al. 2010). Physical factors will influence the relationship, e.g., the presence of multiple sources for effusion (e.g., Lavallée et al. 2012) or variations in the morphology as a function of time. Determining what controls the effusion rate at a volcano involves the consideration of a complexity of variables. Modelling has produced some insight into the processes, for example, taking a simple geometric model and simulating an increase in pressure within the magma chamber have been shown to influence the effusion rate (de' Michieli Vitturi et al. 2010). Increases in effusion rate can have a critical influence on the risks as was witnessed at Soufrière Hills, where an increase has resulted in large increases in eruptive activity, either as Vulcanian explosions or potentially dangerous pyroclastic flows descending the flanks.

Estimating the effusion rate of a volcano can prove to be a challenge. If the magma extrusion results in purely dome growth, an estimation of the volume variation over time is sufficient. This can be carried out using photogrammetry, with recent software advances allowing the use of standard cameras to produce digital elevation models to an accuracy of around 5 % (Diefenbach et al. 2012; James and Varley 2012). Maintaining an acceptable accuracy becomes difficult once the dome extends to lava flows or when the loss of material through rockfalls becomes significant. Although estimating the area of a lava flow presents no problems, the height usually remains largely unknown, and estimates typically assume a fairly arbitrary and constant thickness, whereas in reality this will vary as a function of the gradient. It is difficult to calculate the volume lost through rockfalls, whereby estimates can only be made in the case of particularly favourable conditions (Mueller et al. 2013).

Rockfalls can also represent precursors for a larger-scale slope failure such as debris flow or debris avalanche. Where there are steep slopes, resulting in free fall of detached material, a linear

relationship is observed between magnitude and frequency in log-log space (Dussauge-Peisser et al. 2002; Rosser et al. 2007), similar to the Gutenberg-Richter relationship for seismicity. This power law for the volume distribution of rockfalls allows the use of statistics to predict the occurrence rates of events of different volumes based on historic records. For the long-term hazards in mountainous regions, this has important implications; however, for dome-derived rockfalls, episodes are usually relatively short in duration lasting just months or in a few cases a few years, making it difficult to compile a reliable volume distribution during the eruption. With frequently active volcanoes, however, if the dome growth has similar characteristics to previously documented episodes, it remains possible to assume repetition of a distribution and hence produce a probabilistic assessment of the hazards. Dussauge-Peisser et al. (2002) published a summary of the *b* values obtained in theirs and other studies when correlating rockfall volume with occurrence (nonvolcanic cases). The volumes range from $0.01\text{--}10 \text{ m}^3$ to $10^7\text{--}10^{10} \text{ m}^3$ and the study periods from 2 months to 10,000 years, with the *b* exponent ranging from 0.40 to 1, but with the majority of values in the range 0.4–0.5. For volcanoes similar time-frequency variations have been observed for pyroclastic flows from Soufrière Hills Volcano, Montserrat (Jolly et al. 2002).

The strain and seismic energy release associated with slope failure should accelerate as a power law (Voight 1988). By examining the increase in seismic energy release over time, it is possible to predict the failure associated with explosive eruptions (Arámbula-Mendoza et al. 2011; Budi-Santoso et al. 2013). For slope failure there is less evidence; however, for Soufrière Hills Volcano, Hammer and Neuberg (2009) showed that swarms of LP events detected prior to dome collapses showed an increase in magnitude that followed the material failure law, thus verifying this method as a potential tool to predict these major collapse events. However, Bell et al. (2011) argue that the failure forecast method is unreliable and that the non-Gaussian distribution of errors needs to be

Rockfall Seismicity Accompanying Dome-Building Eruptions, Fig. 8 Typical seismic waveform from a rockfall with spectrum from Soufrière Hills Volcano, Montserrat in 2007 (figure prepared by Silvio De Angelis)

considered. They suggest the use of a generalized linear model, which is a generalization of least-squares linear regression.

Generation and Characteristics of Seismicity

Due to the vastly superior body of work, initially seismicity from nonvolcanic mass movements is considered here. The differences between these distinct types of events and those derived from volcanic domes are minimal. During the transport of material down steep slopes, part of the energy transferred becomes seismic energy producing characteristic waves. The proportion of potential energy transformed into seismic energy is small, with estimates varying from 0.25 (Vilajosana et al. 2008) to between 10^{-6} and 10^{-3} (Deparis et al. 2008; Hibert et al. 2011).

A typical seismic signal generated from a mass movement event has an elongated symmetric gradually increasing then decreasing waveform; the initial steady acceleration in the liberation of energy results in emergent seismic signals (e.g., Pankow et al. 2014). The position of the peak within the waveform should be related to the time when the largest volume is in motion on the slope, producing the largest number of impacts with the ground (Dammeier et al. 2011). There might be a wide variety of block size, shape, and initial location on the slope, producing diverse durations of individual

transport times and extending the overall event duration. Whereas the generation of tectonic seismic events is modelled by double-couple or moment tensors, seismicity generated by landslides or rockfalls has been modelled as single force (Fukao 1995).

For rockfalls the spectral content is wide (1–20 Hz) but will depend upon the source-station distance, with a larger distance implying larger low-frequency content due to the attenuation being frequency dependent (Suriñach et al. 2005). Path and source effects will influence the signal recorded, particularly since the source is moving at a high velocity, so its direction in relationship to the seismometer location will have a large effect. The majority of energy tends to be concentrated below ~ 3 –4 Hz and the higher frequencies might be generated by the collision between blocks (Dammeier et al. 2011). Figures 8 and 9 show typical rockfall waveform and spectrum from Soufrière Hills Volcano in 2007 and Volcán de Colima in 2013.

Examination of the seismicity generated by landslides has determined differing characteristics for different wavelengths, with low-frequency components being detected prior to high frequency with their peak also occurring earlier (Yamada et al. 2012). The topography can significantly influence the seismic signal, as can the rheology of the flow (Favreau et al. 2010). Due to the emergent waveform, the uncertainty of the first arrival makes it more difficult to estimate the location of the event or calculate the

Rockfall Seismicity Accompanying Dome-Building Eruptions, Fig. 9 Typical seismic waveform from a rockfall with spectrum and spectrogram from Volcán de

Colima during small dome collapses in 2013 (figure prepared by Raúl Arámbula)

magnitude of the seismicity using standard seismic methods. The local M_L and coda or duration magnitude m_d can be calculated using an assumed location. Large values for the difference between these calculated magnitudes $M_L - m_d$ are a characteristic of seismicity from surface events. However, successful source location has been achieved, for example, in the case of Piton de la Fournaise volcano (Hibert et al. 2011). It is possible to record the signal from large dome collapses at quite a distance. Long-period seismic signals were generated by the 1997 collapse at Soufrière Hills Volcano and recorded at stations 450 and 1,261 km away. Modelling permitted the description of the avalanche event as two horizontal and one vertical force, the transition between each force occurring over a period of 70 s (Zhao et al. 2013).

Utility of Rockfall Seismicity

As with any application of seismicity, the availability of information is a function of the network configuration and response of each seismometer. With a large network including closely located stations, analyses of the seismicity of mass movements can provide a wealth of information, including the source of the rockfall. For volcanoes, this can be important since the risk presented by an event descending one flank is likely to be distinct to another. In an artificially generated rockfall, it was shown that a suitable configured network of broadband stations could be used to take advantage of the linear polarization of the P-waves of a rockfall to obtain a location and size estimate for rockfalls (Vilajosana et al. 2008). Recently an automated

system has been developed at Piton de la Fournaise Volcano, Reunión, to not only locate events but to estimate their volume (Hibert et al. 2014). Using the technique of fuzzy sets, a success rate of 92 % has been achieved.

The application of rockfall seismicity to mitigate the associated risk can be divided into several areas:

Monitoring of Slope Conditions

The application of seismic networks for monitoring slope conditions at open-cast mines has generated abundant data in the event of slope failure. An enormous $65 \times 10^6 \text{ m}^3$ landslide occurred at the Bingham Canyon copper mine in the USA in 2013 (Pankow et al. 2014). In this case, seismometers that detected the event were located between 6 and 400 km. The landslide, classified as a rock avalanche, was actually two closely spaced events. The seismicity was dominated by long-period events with differences between the two episodes: only the first one produced a high-amplitude peak near the end of the coda and there was a large difference when the maximum amplitude occurred.

Retrospective Analysis of Mass Movement Events

The simplest application of seismicity is as a means of estimating the duration and velocity of avalanches. Incorporating spectral analysis extends the possibility, with long-period seismicity in particular having provided important insights into the physical characteristics of flows, e.g., erosive processes of the 40–60 Mm^3 Mount Steller, Alaska, rock-ice avalanche were qualitatively described (Moretti et al. 2012).

The volume of a moving mass can be estimated by quantifying the seismic energy. Yamada et al. (2012) formulated an empirical relationship which correlated approximately the square of the volume with the energy parameter. It is important to note that in general a specific relationship derived for one location will be explicit for that location, though attempts have been made to formulate more widely applicable correlations between different characteristics. Just taking five basic parameters of the seismicity

(duration, peak magnitude, velocity envelope area, rise time, and average ground velocity) Dammeier et al. (2011) obtained relationships with five fundamental rockslide event parameters: volume runout distance, drop height, and potential energy, for a series of different events. Particularly using the first three parameters, they suggested their results could be adapted to allow event characterization from seismic data. Obviously for risk mitigation, the volume and runout distance of a collapse event represent the most important parameters.

With more complex analysis, further dynamic information can be obtained about mass movement events. Suriñach et al. (2005) observed an increase in time of the higher frequencies of the seismicity associated with landslides. When the direction of the movement is toward the seismometer, a decrease in the attenuation of higher frequencies with increasing distance from the source would result in this pattern.

Seismicity associated with avalanches has been used to calibrate a model to describe its motion (Schneider et al. 2010). One of the events studied was on an Alaskan volcano, Iliamna, which typifies the more simple topography when comparing volcanoes with mountains. This results in a simpler seismic signal from any mass movement down its flanks. This type of model produces an estimate of the inundation zone of the avalanche. In the case of an erupting lava dome, the volatiles being released from the magma upon decompression will make a pyroclastic density current more likely than a less mobile avalanche.

Precursors of Eruptions

The quantification of rockfall frequency can make a useful contribution to volcano monitoring, with significant increases possibly representing precursors to enhanced activity. At Augustine, USA, rockfall-generated seismicity was recorded from 1997 to 2009 and revealed a typical duration of 30 s for rockfall events, with their frequency $>4 \text{ Hz}$ (DeRoin and McNutt 2012). The number of annual events increased dramatically from an average of 28 per year up to 340 in 2005, which was precursory to an

eruption which started in early 2006. Subsequently there were rockfalls during the growth of a lava dome and its frequent collapse. Instability of the dome meant the continuation of rockfalls after effusion had ceased. Also in Alaska at Iliamna, for some ice-rock avalanches seismic precursors were recorded, demonstrating the value of seismic monitoring of hazardous collapse events (Huggel et al. 2007).

Studies of Eruption Processes

Detailed examination of the characteristics of the seismicity associated with rockfalls has been used to understand the mechanism of the destabilization process and collapses (De Angelis et al. 2007; West 2013). The amalgamation of the fields of rock mechanics and volcano seismology is resulting in a far more detailed understanding of the generation process of rockfalls or pyroclastic flows. Studies of time series of rockfalls can provide important information regarding the evolution of the eruptive process. Their associated seismicity provides a convenient method to identify their occurrence in time. Calder et al. (2005) looked at the repose period between rockfalls generated by the growing of Soufrière Hills Volcano, Montserrat. They determined that a log-logistic probabilistic density function fitted the data, which reflects the failure mechanism. Within the seismic classification scheme at Soufrière Hills Volcano, two distinct rockfall classes are defined: normal rockfalls and long-period rockfall signals (Luckett et al. 2002). The latter are thought to be produced by the superposition of two phenomena, violent degassing on the dome surface triggering a nearby rockfall. For pyroclastic flows descending the flanks, the seismicity was used to estimate the location of the flow from its onset thus proving values for their extension and speed (Jolly et al. 2002).

At Augustine, Alaska, rockfalls were observed to follow a seasonal pattern, with rainfall having some influence (DeRoin and McNutt 2012), an important information for risk mitigation.

A special case of volcanic rockfall, not associated with dome growth, is the events arising from instabilities in the walls of pit craters which can occur at basaltic volcanoes. Very

long-period events have been identified as being generated from rockfalls within the pit crater at Kilauea (Chouet and Dawson 2013). The idea behind their generation mechanism is oscillation of the conduit and inversion of the waveforms provided the volume of the rockfalls ($200\text{--}4,500\text{ m}^3$) as well as the dimensions of the magma column, dyke system, magma flow rate, and its viscosity.

For volcanoes, a direct correlation between rockfall frequency and effusion rate has often been assumed but studies quantifying the two parameters are virtually nonexistent. To quantify the volume of rockfalls using seismicity, first the relationship between the two needs to be established. It was observed that the seismic magnitude correlated with the rockfall volume at Mt. St. Helens on the same slope (Norris 1994). Mueller et al. (2013) estimated the effusion rate of Volcán de Colima by observing directly the volume of material lost by the dome in various rockfalls. The associated seismicity was calibrated by comparing both the duration and the integrated energy with the estimated rockfall volume. At this time the overall dome was not increasing in volume, but fresh magma produced an exogenic lobe located on the steep western side with emplaced material all lost in rockfalls.

One study carried out at Piton de la Fournaise, Réunion, analyzed hundreds of events and established a relationship between rockfall volume and the seismic signal (Hibert et al. 2011). These rockfalls occurred from the steep crater walls of the basaltic volcano during periods of inflation and deflation rather than from lava emplacement.

Summary

Growing lava domes can be hazardous with the possibility of large collapses impacting the surrounding area. The characteristic seismicity produced during rockfalls can be used to determine important parameters associated with the eruption, such as the calculation of the rate of effusion, or to understand the processes associated with lava emplacement. Studies of the seismicity

therefore represent an important component of risk mitigation. In this entry results from studies of nonvolcanic rockfalls and other mass movements are presented and compared to the seismicity measured for their volcanic counterparts. The factors controlling the emplacement of domes are briefly summarized, along with how the seismicity is generated and then utilized in volcano monitoring.

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding

Panayiotis C. Polycarpou and

Petros Komodromos

Department of Civil and Environmental Engineering, University of Cyprus, Nicosia, Cyprus

Synonyms

Adjacent buildings; Collision; Elastomeric pads; Impact; Neighboring buildings; Rubber bumpers; Seismic gap; Seismic isolation; Standing distance

Introduction

In densely resided areas and city centers, neighboring buildings are usually constructed very close to each other without adequate clearance between them. Therefore, during strong earthquakes, structural pounding may occur between adjacent buildings, due to deformations of their stories “► [Learning from Earthquake Disasters](#).” Consequences of such pounding occurrences, ranging from light local damage to severe structural

damage or even collapse, have been observed and reported in past strong earthquakes “► [Post-Earthquake Diagnosis of Partially Instrumented Building Structures](#)” (Anagnostopoulos 1995; Bertero 1987; EERI 1990, 2000). In case of structural pounding, both floor accelerations and interstory deflections may be significantly amplified, threatening the functionality and the contents of the building (Papadrakakis and Mouzakis 1995; Anagnostopoulos 1988; Komodromos et al. 2007). The photograph in Fig. 1 shows a pounding incidence between two adjacent buildings, as reported from an EERI/PEER reconnaissance team after the L’Aquila Earthquake, which hit Central Italy in April 2009 (EERI 2009). During that seismic event, the roof of a two-story building hit an adjacent four-story structure causing considerable damage to the columns of the latter at that level. However, the third and the fourth stories of the building did not experience any significant damage. The limitation of the damage of the four-story building at the level of impact indicates the destructive effect of structural pounding.

Furthermore, pounding may also take place in cases of seismically isolated buildings, which exhibit quite different dynamic characteristics from conventionally fixed-support buildings. In particular, pounding of a seismically isolated building occurs primarily as a consequence of the large relative displacements at the isolation level (Fig. 2), due to the excess flexibility that is provided there through the seismic isolators rather than due to the deformation of the superstructure. This fact, in combination with a limited width of the seismic gap that is provided around the building, results in impacts between the structure and the surrounding moat wall during very strong, near-source “► [Seismic Sources from Landslides and Glaciers](#)” seismic excitations (Komodromos et al. 2007).

At the pounding floors, short-period impulses of high amplitude are observed in the acceleration response, while their amplitude is affected by the impact stiffness. The presence of high spikes in the acceleration response due to structural pounding is a very critical issue, especially for buildings that may house sensitive equipment.

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 2 (a) Configuration of a seismically isolated building; (b) Mode of deformation during an earthquake

Therefore, it is very vital to consider potential impact mitigation measures that could be employed in practice.

Certain mitigation measures have already been proposed by other researchers who investigated this problem in buildings and bridge decks, in an effort to alleviate the damaging effects of

structural pounding (Warnotte et al. 2007). One of the proposed measures is the incorporation of layers of soft material, such as elastomeric material, on certain locations, where impact is likely to occur, in order to act as a shock absorber. The idea is based on similar measures that are usually taken in ports or harbors, where soft bumpers are

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 3 Rubber shock absorber attached within the seismic gap of a seismically isolated building in Cyprus

attached at the wharfs in order to avoid damage on the docking ships due to collisions with the docks. Figure 3 shows a case of applying rubber bumpers in the seismic gap of a seismically isolated building located in Nicosia, Cyprus. The incorporated rubber shock absorbers can act as restrainers to prevent larger horizontal displacements than the seismic isolators can accommodate and avoid sudden impact pulses due to potential structural pounding. However, there is a question about the effectiveness of this technique, since the introduction of such material, with a certain thickness, reduces accordingly the width of the available seismic gap between the colliding structures. It is widely known that the width of the seismic gap affects significantly the dynamic response during pounding and, specifically, as the width of the seismic gap increases the detrimental effects of pounding are generally alleviated.

In order to assess the effectiveness of such an impact mitigation measure, proper numerical simulations and parametric studies are needed, considering various types and configurations of structures under different dynamic excitations. Nevertheless, the behavior of rubber shock absorbers under impact loading must be sufficiently well modeled. Undoubtedly, the most precise modeling can be achieved with the development of a detailed finite element model using special elements and material laws to

properly represent the nonlinearity of the problem. However, such simulations are computationally very demanding and cannot be effectively employed for a parametric investigation of the problem. Therefore, an impact model should be used in numerical simulations of simple multidegree of freedom dynamic systems, which will be able to provide, with sufficient accuracy, the pounding forces considering the usage of rubber shock absorbers at impact locations (Polycarpou and Komodromos 2009, 2013). In the following paragraphs, an efficient methodology for simulating the behavior of rubber bumpers of certain thickness and material properties is described.

Impact Modeling

Usually, in numerically simulated dynamic systems, such as multistory buildings under earthquake excitations, structural impact is considered using force-based methods, also known as “penalty” methods. These methods allow relatively small interpenetration between the colliding structures, which can be justified by the local deformability at the point of impact. The interpenetration depth is used together with an impact stiffness coefficient, which represents an impact spring, to calculate the impact forces that act on the colliding structures and push them apart.

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 4

The modified linear viscoelastic impact model, used for simulating concrete-to-concrete impacts

Based on the mathematical relation between the impact force and the interpenetration depth, the impact models can be classified as linear and non linear models. Moreover, some models assume that an impact dashpot acts in parallel to the contact spring in order to take into account the energy that is dissipated during an impact (Polycarpou and Komodromos 2010).

Concrete-to-Concrete Impacts

In the proposed methodology, impacts between concrete surfaces are simulated assuming a linear impact spring and an impact dashpot exerting, in parallel, impact forces to the colliding structures whenever their separation distances are exceeded. In particular, when a contact is detected, the impact force is estimated at each time step using the following formulas (Komodromos et al. 2007):

$$F_{imp}(t + \Delta t) = \begin{cases} k_{imp} \cdot \delta(t) + c_{imp} \cdot \dot{\delta}(t) & \text{when } F_{imp}(t) > 0 \\ 0 & \text{when } F_{imp}(t) \leq 0 \end{cases} \quad (1)$$

where $\delta(t)$ is the interpenetration depth, $\dot{\delta}(t)$ is the relative velocity between the colliding bodies, k_{imp} is the impact spring's stiffness, and c_{imp} is the impact damping coefficient. The latter is computed according to the following formulas, provided by Anagnostopoulos (1988):

$$c_{imp} = 2 \cdot \xi_{imp} \sqrt{k_{imp} \cdot \frac{m_1 \cdot m_2}{m_1 + m_2}} \quad (2)$$

$$\xi_{imp} = -\frac{\ln(COR)}{\sqrt{\pi^2 + (\ln(COR))^2}} \quad (3)$$

In the aforesaid formulas, m_1 , m_2 are the masses of the two bodies and COR is the coefficient of restitution, which depends on the plasticity of the impact and is defined as the ratio of relative velocities after and before impact. Its value rates between 0, which corresponds to totally plastic impact (without rebound), and 1, which represents

the case of elastic impact. An estimated value of the coefficient of restitution has to be provided before the analysis, taking into account the geometry and material characteristics at the vicinity of the impact. For example, the value of the COR, for the case of structural pounding between concrete structures, is commonly set to a value between 0.5 and 0.7. Actually, the above impact model (Fig. 4) is a small variation of the classical linear viscoelastic impact model that had been initially proposed by Anagnostopoulos (1988), in which the tensile forces that arise at the end of the restitution period are omitted and a small plastic deformation is introduced, which increases the available clearance between the adjacent structures.

Modeling of Rubber Bumpers – Proposed Impact Model

A significant part of this numerical problem has to do with the simulation of the behavior of

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding,

Fig. 5 Experimental results, involving both static and impact tests of rubber shock absorbers, (Obtained from Kajita et al. (2006))

rubber bumpers under impact loading. The usage of linear impact models for simulating the response of rubber during impact loading does not seem to be the most suitable, considering the stress–strain curves obtained from experiments (Kajita et al. 2001, 2006; Kawashima et al. 2002; Shim et al. 2004). In particular, static and dynamic compressive tests of rubber reveal an exponential relationship between the compressive load and the corresponding displacement, as shown in the plots of Fig. 5. Therefore, it would be more appropriate to simulate the incorporation of rubber bumpers by using a nonlinear impact model. Furthermore, since a rubber shock absorber has a finite thickness, there is a possibility to reach its ultimate compressive strain during severe impacts, whereas the impact stiffness should represent the material behind the rubber (e.g., concrete) and not the rubber bumper, after the ultimate strain of the rubber is exceeded.

Subsequently, a new impact model is proposed in the following paragraphs, taking into account the observations from relevant impact

tests as well as the special characteristics of rubber bumpers. Specifically, the proposed nonlinear impact model assumes that the impact force is increasing exponentially with the interpenetration depth during the approach phase of impact, which is very close to the profile of the stress–strain curves obtained from the corresponding experiments. In order to take into account the dissipation of kinetic energy during impact, a different path of the force–displacement curve is followed during the restitution phase, forming a hysteresis loop (Fig. 6). In particular, the impact force for a certain indentation value during the detaching phase is reduced compared to the corresponding impact force for the same indentation during the approach phase. Actually, this reduction, which depends on certain parameters, such as the material characteristics and the impact velocity, determines the area of the hysteresis loop and, therefore, the amount of dissipated energy during impact. The impact force during the approaching phase is provided by the formula

$$F_{imp}^A = \left\{ \begin{array}{ll} k_{imp} \cdot \delta^n & \text{for } \delta < \delta_u \\ k_{imp} \cdot \delta_u^n + k_{imp_PY} \cdot (\delta - \delta_u) & \text{for } \delta > \delta_u \end{array} \right\} \text{ when } \dot{\delta} > 0 \quad (4)$$

Equation. 4 takes into account the case of exceeding the ultimate compressive strain of the

material, during the approach phase. Specifically, it is assumed that, after a certain indentation, δ_u ,

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 6

Force-displacement diagram of the non-linear impact model with hysteretic damping

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 7

Impact force in terms of time and displacement in the case of exceeding the ultimate compressive strain capacity of the rubber bumper

which corresponds to the ultimate compressive capacity of the rubber bumper, the exponential trend becomes linear with a linear postyield stiffness, k_{imp_PY} (Fig. 7).

During the restitution phase, the impact force is described by the following expression:

$$F_{imp}^R = k_{imp} \cdot \delta^n \cdot (1 + C_{imp} \cdot \dot{\delta}) \quad \text{for } \dot{\delta} < 0 \quad (5)$$

In Eq. 4, k_{imp} is the impact stiffness, δ is the indentation, and n is the impact exponent ($n > 1$). The dot over δ denotes derivation with respect to time, so $\dot{\delta}$ represents the approaching relative velocity of the colliding bodies. The impact stiffness is given by the following expression:

$$k_{imp} = \alpha \cdot k_{st} = \alpha \cdot \frac{A \cdot K_r}{d^n} \quad (6)$$

where k_{st} is the bumper's static stiffness and $\alpha > 1$ is a multiplier that expresses the strain rate dependency of the material stiffness, and for simplicity, it can be assumed that it ranges between the values of 2 and 2.5 for common earthquake-induced structural pounding velocities, based on relevant experimental results (Kajita et al. 2006). A is the contact area of the bumper, d is the bumper's thickness, and K_r expresses the material stiffness. The unknown parameters that have to be determined in Eq. 6 are the material stiffness K_r and the exponent n . The values of both parameters depend on the material characteristics, and therefore, their evaluation can be done experimentally. In particular, a static test curve of a rubber specimen (see, e.g., Fig. 5a) can be approximated with an exponential curve of the form

$$f(x) = c \cdot x^b \quad (7)$$

In this way, c can represent k_{st} , while b can represent the exponent n . Then, the material stiffness can be calculated by substituting these values in Eq. 6 and solving for K_r . After obtaining the material properties K_r and n , the impact stiffness of any rubber bumper with the same material and any dimensions can be calculated using Eq. 6.

The damping term C_{imp} in Eq. 5 is given by the formula (Polycarpou et al. 2013)

$$C_{imp} = \frac{(1 - COR^2)}{2 \cdot v_{imp}} \cdot \frac{\ln^3(COR)}{COR \cdot (2 + \ln^2(COR) - 2 \cdot \ln(COR)) - 2} \quad (8)$$

where v_{imp} is the impact velocity, which is the relative velocity of the two bodies just before impact.

The force-time and force-displacement diagrams of the proposed nonlinear model for simulating the response of rubber bumpers under impact loading are shown in Fig. 6. Figure 7 demonstrates the same diagrams in the case of exceeding the ultimate compressive capacity of the bumper for three different values of the coefficient of restitution.

Impact Model's Validation and Parameters' Determination Based on Experimental Data

In order to validate the accuracy of the proposed nonlinear hysteretic impact model, the load-displacement curves obtained from the collision tests are compared with the corresponding results from numerical analyses, simulating the impact of two free bodies and considering the proposed impact model. The estimation of the impact parameters is based on the static load-displacement curve of the rubber that was used in the experiments. In particular, the static test curve is approximated with an exponent $n = 2.65$ and a static stiffness $k_{st} = 0.2 \text{ kN/mm}^{2.65}$. Consequently, considering the dimensions of the shock absorber that was used in the experiments ($40 \times 40 \times 10 \text{ mm}$) and substituting to Eq. 6, the material's stiffness K_r is found to be equal to $55,835 \text{ kN/m}^2$. The strain rate multiplier α is taken to be equal to 2.25, and thus, the impact stiffness for the dynamic response is calculated through Eq. 6 to be equal to $0.45 \text{ kN/mm}^{2.65}$. The energy loss during similar impact tests was found to range around 40–50 % of the initial kinetic energy when using the rubber shock absorbers (Kajita et al. 2001). Accordingly, the coefficient of restitution is assumed to be equal to 0.5 for the simulations. Nevertheless, the value of the coefficient of restitution, in the proposed impact model, does not affect the value of the maximum impact force but only the trend of the restitution phase, determining the hysteretic energy loss.

The plots in Fig. 8 present the experimental results from Kajita et al. (2006) in comparison with the corresponding numerical results, obtained from the performed simulations considering the proposed nonlinear hysteretic impact model for the simulation of the rubber bumpers. In particular, the force-displacement diagrams are presented for the static test and three different impact velocities, considering an impact shock absorber of 10 mm thick attached between two colliding masses of 300 kg each. It is observed that the trends obtained from numerical analysis, using the proposed impact model, correlate very well with the corresponding experimental data. In particular, there is a good approximation of the maximum impact force as well as the shape and

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 8 Comparison between experimental and numerical force-displacement

diagrams of a 10 mm thick rubber shock-absorber for various impact velocities

size of the hysteresis loop of the proposed impact model with the corresponding experimental results.

Numerical Example Considering Two Rigid Bodies

In order to examine the effect of using a rubber shock absorber on the computed responses after impact, a simple numerical example of two free rigid bodies of equal masses that collide with a constant relative velocity has been performed. Two different circumstances have been considered regarding the area of contact. In the first case, concrete-to-concrete impact was considered and the modified linear viscoelastic impact model was used (Eq. 1). In the second case, a rubber bumper 5 cm thick was assumed to be incorporated at the area of contact, which is simulated using the nonlinear impact model with hysteretic

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Table 1 Impact parameters for the cases without and with rubber bumper

Property	No bumper	With bumper
Impact model	Linear	Non-linear
Exponent (n)	1.0	2.65
Impact stiffness (k_{imp})	2,500 kN/mm	0.36 kN/mm ^{2.65}
Coefficient of Restitution (COR)	0.6	0.5
Bumper thickness (d)	—	5 cm
Bumper's max strain (δ_u/d)	—	0.8
Post-yield impact stiffness (k_{imp_PY})	—	2,500 kN/mm

damping (Eqs. 4 and 5). The impact parameters that were used in both cases are provided in Table 1. The masses of the two colliding rigid structures are assumed to be 320 t each, while two different values of impact velocity were used, specifically 0.5 and 1.0 m/s.

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 9 Impact force – displacement diagram for the cases of two

impacting rigid bodies, with and without the incorporation of a rubber bumper and for two different values of the impact velocity

Figure 9 demonstrates the load–displacement diagrams for the two cases of the impact velocity and for both cases of with and without the use of the rubber bumper. The results show that the indentation, which represents the local deformation at the vicinity of an impact, is much larger in the case of having the rubber shock absorber due to the reduced impact stiffness. Furthermore, in the case of the relatively high impact velocity of 1.0 m/s, the deformation exceeds the maximum compressive capacity of the 5 cm thick rubber bumper, and the impact force begins to rise rapidly, since the postyield linear impact stiffness is used.

The plots in Fig. 10 show the impact force, relative velocity, and acceleration time histories for the same cases. It is evident that the usage of the rubber bumper elongates the duration of impact and reduces both the maximum impact force and the maximum acceleration. The ratio between the relative velocity after and before impact is equal to the coefficient of restitution used in the corresponding impact model, which verifies the correctness of the two impact models used in the simulations.

Although the use of rubber bumpers seems to be an effective impact mitigation measure in the case of two colliding free bodies, its effectiveness has to be assessed in the case of earthquake-induced pounding of adjacent buildings, since

the incorporation of the bumpers reduces the available seismic gap, increasing the possibility of pounding. For this purpose, two practical examples are presented in the following paragraphs in order to assess the effectiveness of using rubber shock absorbers as an impact mitigation measure for both cases of seismically isolated and conventionally fixed-support buildings. For the numerical simulations, a specialized software application has been developed using modern object-oriented programming in order to efficiently perform dynamic analyses of buildings in two dimensions “► [Time History Seismic Analysis](#)” modeling the consideration of potential poundings with adjacent structures.

Application Example Using a Seismically Isolated Building

A four-story seismically isolated building is considered in this example, assuming shear beam behavior for the superstructure and bilinear behavior for the base isolation system “Elastomeric Bearings and their Implementation into Structural Design and Analysis” (Fig. 11). The initial seismic gap around the building is considered to be equal to 25 cm. The same building is considered under a second configuration, where rubber shock absorbers of 5 cm thick are

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 10 Impact force, relative velocity and acceleration time-histories for the

case of two impacting rigid bodies, with and without the incorporation of a rubber bumper and for two different cases of the impact velocity

attached around the building at the isolation level, with a clearance of 20 cm.

For the case without the use of bumpers, where the building hits against the surrounding moat wall (concrete-to-concrete impact), the linear viscoelastic impact model is used with an impact stiffness of 2,500 kN/mm and a coefficient of restitution equal to 0.7. In the case of incorporating the rubber shock absorbers, the proposed nonlinear hysteretic impact model is used with an exponent $n = 2.65$, $k_{imp} = 0.36$ kN/mm^{2.65} and a $COR = 0.45$. The impact stiffness of the

bumpers was calculated using Eq. 6, considering four pieces of rubber with an area of 15 cm × 15 cm each, attached at each side of the seismically isolated building (Fig. 12). The Sylmar Converter Station record “► [Recording Seismic Signals](#)” ($PGA = 0.897g$) of the Northridge 1994 earthquake ($M_w = 6.7$) is used as the ground excitation for the simulations. For the seismically isolated building under consideration, the maximum induced unconstrained displacement at the isolation level due to this earthquake record is 31.67 cm.

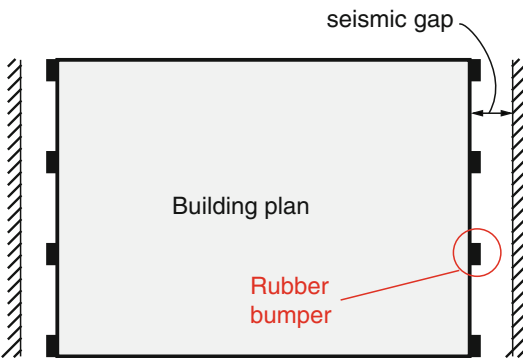

c

Parameter	Value
Story stiffness (k_i)	600 MN/m
Story mass (m_i)	320 ton
Top story mass (m_n)	250 ton
Superstructure's damping ratio (ξ_{sup})	2%
Mass at isolation level (m_{iso})	320 ton
Isolation's viscous damping ratio (ξ_{iso})	5%

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 11 (a) Model of a seismically isolated building; (b) Bilinear model of the

isolation system behavior; (c) Structural properties of the considered seismically isolated building

R

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 12 Locations of rubber shock absorbers in a plan view of the building

Figure 13 presents the acceleration time histories at the base of the seismically isolated building, where poundings occur, for both cases, without and with bumpers. Although in the case of having bumpers the available clearance is reduced from 25 to 20 cm, it is observed that the maximum acceleration response is lower than the corresponding peak acceleration without bumpers. In particular, the high spikes in the acceleration response seem to be eliminated due to the usage of the rubber shock absorbers.

This can be explained by observing the impact force time history as presented in Fig. 14.

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 13 Differences on the acceleration time-history at the isolation level due to

the attachment of 5 cm wide rubber shock absorbers the impact locations

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 14 Differences on the impact force time-history at the isolation level due to

the attachment of 5 cm wide rubber shock absorbers at the impact locations

Specifically, the plot indicates that the impact forces in the case of adding bumpers not only become smaller but also the duration of the impact is longer, smoothening the acceleration response at the corresponding floor level.

Figure 15 displays the maximum responses at all floors of the seismically isolated building for the two configurations examined, i.e., with and without rubber bumpers, as well as the case of having a seismic gap of 20 cm without using bumpers.

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 15 Differences on the maximum responses of the seismically isolated

building due to the attachment of 5 cm wide rubber shock absorbers at the impact locations

While for the case of reducing the seismic gap size to 20 cm without adding any bumpers, the response is substantially amplified, no significant increase of the maximum interstory deflections or the maximum floor acceleration at the upper floors were observed due to the decreased gap size when rubber bumpers are used. On the contrary, the maximum interstory deflection at the first story, which is the largest among all stories, slightly decreases after the incorporation of the rubber. Nevertheless, it has to be mentioned that these observations concern only the specific earthquake excitation and the specific seismically isolated building. There is a need for further investigation, performing numerous simulations considering different characteristics of the structures and different earthquake records, where the effectiveness of such impact mitigation measures will be more generally assessed.

Application Example and Parametric Analyses Considering Two Conventional Fixed-Supported Buildings

Next, another example is presented to examine also the case of using rubber shock absorbers as

an impact mitigation measure for cases of narrow seismic gap sizes between adjacent multistory conventionally fixed-support buildings. Again, the simulated buildings are modeled in 2D as multi-degree of freedom (MDOF) systems, with shear beam behavior and the masses lumped at the floor levels, assuming linear elastic behavior during earthquake excitations.

A four-story and a six-story fixed-support buildings are considered in series for the performed simulations, as shown in Fig. 16. Each floor has a lumped mass of 320 t, except the top floor where a mass of 250 t is considered. Each story has a horizontal stiffness of 600 MN, while a constant viscous damping ratio of 5 % has been considered for both buildings. The floors of the neighboring buildings are assumed to be at the same levels.

For the particular structural system, the performed analysis examined whether the incorporation of rubber bumpers at the locations of potential impacts, which reduces the available seismic gap width, would be beneficial for the colliding buildings or not. For the performed simulations, 5 cm thick bumpers were assumed to be installed at all floor levels, as shown in Fig. 16. Therefore, by applying the rubber shock

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 16

The two multistory buildings considered in the simulations and their structural properties

absorbers at the side of one of the two buildings, the existing seismic gap size reduces by 5 cm, when compared with the case without the bumper. Consequently, the results obtained from the simulations considering the use of rubber bumpers are compared with the corresponding results from the case without bumpers but with a clearance that is 5 cm wider. In the performed parametric analyses, the available seismic gap was varied in the range of 5–25 cm, which corresponds to a clearance width of 0–20 cm in the case of incorporating rubber bumpers.

In order to investigate the effect of the earthquake characteristics, three different seismic records (Table 2) from relatively strong and widely known earthquakes were selected and used as ground excitations.

Plots in Fig. 17 demonstrate the effect of using rubber bumpers on the computed response of the four-story and the six-story buildings, in terms of the size of the seismic gap for the Kobe earthquake record. In particular, the plots present the amplification of the peak floor accelerations and peak interstory deflections due to the incorporation of rubber shock absorbers with a thickness of 5 cm, between the two buildings. The

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Table 2 Earthquake records that were used in the simulations

Earthquake	Mw	Recording station	P.G.A. (g)
Kobe, Japan 1995	6.9	0 KJMA	0.821
Northridge, USA 1994	6.7	74 Sylmar – Converter	0.897
San Fernando, USA 1971	6.6	Pacoima Dam, S16	1.170

amplification of the response is defined as the ratio of the response obtained after the incorporation of rubber bumpers, which unavoidably reduce the available clearance, to the corresponding response, without the usage of bumpers. Therefore, the usage of rubber bumpers has beneficial effects on the corresponding response quantity when the amplification ratio value is smaller than 1.0.

The results indicate that the size of the seismic gap affects the effectiveness of the rubber bumpers in a different manner on each floor and for each building. For example, the peak floor acceleration at the fourth floor of the four-story

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 17 Amplification of the peak floor accelerations and interstory deflections of

the 4-story and the 6-story buildings, due to the usage of rubber shock-absorbers, in terms of the width of the seismic gap, considering the Kobe earthquake record

building is reduced after the incorporation of the bumper almost for all seismic gap sizes, while at the same time the peak acceleration at the second floor of the six-story building amplifies up to 30 %. Moreover, the maximum interstory deflections are not affected in the same way with the floor accelerations, since the latter may be amplified after the use of the rubber bumper, while the former are reduced for a certain gap size. Nevertheless, peak floor accelerations seem to be more sensitive to the usage of bumpers than interstory deflections, since the variations of the curves in the plots of Fig. 17 are more pronounced in the former case.

In order to be able to provide the computed results from all three earthquake records in the same plots, the mean peak responses among all floors of the buildings are computed and plotted in Fig. 18. Specifically, these plots demonstrate, in a more general form, the effect of applying rubber bumpers of 5 cm thick inside the available

gap on the overall seismic response of the two buildings. It is observed that the characteristics of the earthquake excitation affect the effectiveness of this kind of an impact mitigation measure, in combination with the size of the available clearance. It can be also observed that, under the considered circumstances, the incorporation of such a shock absorber amplifies, in most of the times, the response, especially in the case of the six-story building. However, there are some cases of relatively narrow gap sizes in which the usage of rubber bumpers seems to be beneficial.

In the previously presented simulations, it has been assumed that, after the attachment of rubber bumpers on the side of the seismically isolated building, the reduction of the available clearance from the surrounding moat wall equals the corresponding thickness of the bumpers. However, the rubber bumpers could be attached in small cavities on the buildings' walls, taking full advantage of the compressible width of the

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 18 Mean values of the peak responses among all floors of the 4-story and

the 6-story buildings, due to the usage of rubber shock-absorbers, in terms of the width of the seismic gap

rubber, as shown in Fig. 19, without unnecessarily decreasing further the width of the seismic gap. For example, if the thickness of a rubber bumper is 5 cm and its maximum compressive strain equals 0.8, then the compressible width δ_u of the bumper is 4 cm. Therefore, if the particular 5 cm thick shock absorber is attached in a cavity that is 1 cm deep, its effective width of 4 cm can be fully utilized, without unnecessarily decreasing further the width of the available seismic gap by 1 cm.

The above technique seems to be quite efficient since the corresponding amplification ratios due to the incorporation of the bumpers, shown in Fig. 20, are substantially reduced in relation to those of Fig. 18.

Summary

The current study investigates numerically the possibility of incorporating layers of rubber or other elastomeric material between neighboring

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 19 Attachment of a rubber shock-absorber in a cavity on the building's wall

structures with relatively narrow seismic gaps in order to act as collision bumpers and mitigate the detrimental effects of potential earthquake-induced pounding. The efficiency of this potential impact mitigation measure is parametrically examined, considering both cases of conventionally fixed-support and seismically isolated buildings, which are subjected to various earthquake

Rubber Shock Absorbers as a Mitigation Technique for Earthquake-Induced Pounding, Fig. 20 Mean values of the amplification of peak responses among all floors of the 4-story and the 6-story buildings, due to the usage of

rubber shock-absorbers with 1 cm cavity (full advantage of bumper effective thickness, i.e. 4 cm), in terms of the width of the seismic gap

excitations. The results indicate that only under certain circumstances the incorporation of rubber bumpers in an existing seismic gap can reduce the amplifications of the peak responses of the structures due to pounding. Specifically, the effectiveness of the bumpers depends on the existing gap size in combination with the earthquake characteristics and the structural properties (e.g., number of stories) of the adjacent buildings. The attachment of the bumper in cavities on the building's wall, taking full advantage of the whole compressible width of the rubber, improves their efficiency.

Introduction

Piles are routinely used as foundations to support short-to-medium span bridges and buildings typically over four stories and other structures. Collapse and/or severe damage of pile-supported structures is still observed in liquefiable soils after most major earthquakes such as the 1995 Kobe earthquake (Japan), the 1999 Kocaeli earthquake (Turkey), and the 2001 Bhuj earthquake (India). The failures not only occurred in laterally spreading (sloping) ground but were also observed in level ground where no lateral spreading would be anticipated. A good discussion on the failure modes can be found in Bhattacharya and Madabhushi (2008).

The failures were often accompanied by settlement and tilting of the superstructure, rendering it either useless or very expensive to rehabilitate after the earthquake. Following the 1995 Kobe earthquake, investigations have been carried out to find the failure pattern of the piles. Piles were excavated or extracted from the subsoil, borehole cameras were used to take photographs, and pile integrity tests were carried out. These studies hinted at the location of the cracks and damage patterns for the piles. Of particular interest is the formation of plastic hinges in the piles. This indicates that the stresses in the pile during and after liquefaction exceeded the yield stress of the material of the pile, despite large factors of safety which were employed in the design. Hinges were found to have occurred at various depths along the pile: at the pile head, at the middle of the liquefiable layer, and toward the interface of liquefiable/non-liquefiable layer. In this context it must be mentioned that piles are currently designed with adequate factor of safety for geotechnical load-carrying capacity (maximum allowable load in the pile) and against bending failure. Bending moment can occur in a pile due to lateral loads arising from: (a) inertia load acting at the pile head and (b) kinematic loads from the ground. Further discussion on the dynamics of the problem can be found in Adhikari and Bhattacharya (2008).

Liquefaction of soil around the pile can affect a pile-supported structure in the following ways:

1. A pile will be laterally unsupported in the zone of liquefaction, i.e., no lateral restraint from the soil to the pile in the liquefied zone. As a result, a pile may be vulnerable to buckling instability if the axial load is high enough and the unsupported length of pile is sufficient.
2. The pile will lose its shaft resistance in the zone of liquefaction, i.e., no liquefied soil-pile friction, and as a result the axial load on the pile in the liquefiable zone will increase.
3. The time period of the structure will change due to liquefaction as the foundation becomes flexible. While calculating the period of a building under non-liquefied condition, it is assumed that foundation is rigid, and as a result only the dimensions of the buildings are adequate to obtain the period. However, as soon as a soil liquefies, the time period may increase.
4. The damping of a pile-supported structure also increases during and after liquefaction.

The above mechanisms were verified experimentally by carefully designed model tests and can be found in Bhattacharya (2003), Bhattacharya et al. (2004), Bhattacharya et al. (2005), and Lombardi and Bhattacharya (2014). Bhattacharya (2003) showed through dynamic centrifuge tests that axial load alone can cause a pile to fail if the surrounding soil liquefies in an earthquake and the mechanism being buckling instability.

Lombardi and Bhattacharya (2014) showed through high-quality shaking table tests that the time period of pile-supported structures will increase owing to liquefaction. In the experiments, the soil was liquefied progressively through a broadband white noise signal with increasing magnitude. Furthermore, they also showed that the overall damping ratio of the structures may increase in excess of 20 %. These have important design implications.

All current design methods, such as JRA (1996), NEHRP (2000), IS 1893 (2001), and Eurocode 8 (CEN 2004), focused on bending strength of the pile to avoid bending failure due to lateral loads (combination of inertia and lateral spreading). In contrast to these conventional

design codes, which advocate bending mechanism as the main design consideration, recent research showed that an axially loaded pile can be laterally unsupported in liquefied soils and is susceptible to buckling failure.

Buckling instability under the interaction of axial and lateral loads can be a more critical design consideration because of its sudden nature and sensitivity to imperfection; see, for example, Dash et al. (2010). More recently, Bhattacharya et al. (2009) included the effects of dynamics on the combined axial and lateral loads on a pile foundation. Essentially, piles in liquefied soils may be better regarded as columns carrying lateral loads rather than laterally loaded beams.

In design, beam bending and column buckling are approached differently. Bending is a stable mechanism as long as the pile remains elastic and secondary failure (e.g., local buckling) is not a possibility. This failure mode depends on the bending strength (e.g., yield moment capacity and plastic moment capacity) of the member under consideration. In contrast, buckling is an unstable mechanism and it occurs suddenly and drastically when the elastic critical load is reached. It is the most destructive mode of failure and depends on the geometrical properties of the member, i.e., slenderness ratio, rather than the member strength. For example, steel pipe piles with identical length and diameter but having different yield strengths (e.g., 200 MPa, 500 MPa, and 1,000 MPa) will buckle at similar axial loads but can resist different amounts of bending. In other words, bending failure may be avoided by increasing the yield strength of the material, but it may not suffice to avoid buckling. To prevent buckling failure, there should be a minimum pile diameter depending on the depth of liquefiable soils. Therefore, designing against bending would not automatically satisfy buckling requirements. It is envisaged that there are plenty of existing pile-supported structures that may need retrofitting.

This entry therefore describes a probabilistic and a deterministic method to assess the reliability of pile foundation for a scenario earthquake. Before the methodology is described, a discussion is presented on the main loading on pile foundations during earthquakes in liquefiable soils.

Methodology

Different Stages of Loading on a Pile-Supported Structure During Earthquakes

Figure 1 shows the different stages of loading of a pile-supported structure during a seismic liquefaction-induced event. $P_{gravity}$ (Stage I) represents the axial load on the piles in normal condition. This can be estimated based on static equilibrium. This axial compressive load may increase/decrease further by $V_{inertial}$ due to inertial effect of the superstructure and kinematic effects of the soil flow past the foundation. $H_{inertial}$ is the inertial lateral loads due to the oscillation of superstructure (Stage II and III). Ground movement causes kinematic loads on the pile foundations. This load can be of two types: transient (during shaking, due to the dynamic effects of the soil mass) and residual (after the shaking ceased due to soil flow, often known as “lateral spreading”) (Stage IV). The various forms of feasible failure mechanisms of pile foundations are shear failure, bending failure, buckling instability, and dynamic failure.

Formulation

Bhattacharya (2006) discusses the deterministic approach to determine the factor of safety of pile foundations against the buckling instability failure. Bhattacharya and Goda (2013) developed a probabilistic procedure for determining the occurrence of a buckling failure of existing piled foundations due to a scenario earthquake.

The methodology is based on assessing two length parameters:

1. Critical length of a pile denoted (H_C). Essentially this is the unsupported length of the pile that can sustain without collapse due to combined axial and lateral loading. This can be estimated based on manipulation of the Euler’s buckling load equation considering the correct boundary condition of the pile. Specifically H_C depends on the type and dimension of superstructure (bridge or building), bending stiffness, axial load acting on the pile, dynamic characteristics of

Safety Assessment of Piled Buildings in Liquefiable Soils: Mathematical Tools, Fig. 1 Different stages of loading and failure mechanism of pile during earthquake

Safety Assessment of Piled Buildings in Liquefiable Soils: Mathematical Tools,

Fig. 2 Concept of critical length (H_C) and unsupported length (D_L)

superstructure, and boundary conditions of the pile at the top and bottom of the liquefiable layer.

- Length of unsupported pile due to liquefaction (D_L): this can be obtained based on the depth of liquefaction due to the design earthquake.

Figure 2 shows the concept of the two lengths. Comparing H_C with D_L , potential failure of the underground pile due to buckling is predicted when $H_C < D_L$ (see Figs. 1 and 2). In reliability terms, H_C is the capacity variable, while D_L is the demand term, and thus the failure criterion can be regarded as the limit state function:

$$g = (H_C - D_L) \quad (1)$$

Probabilistic and Deterministic Approach

In a deterministic approach, we obtain a single value of the two parameters and can obtain the factor of safety against failure. However, the advantages of assessing using probabilistic approach are (i) the outcome is expressed as a (estimated) likelihood of failure by taking into account various sources of uncertainty involved in the assessment; (ii) sensitivity analysis can be conducted to identify key factors that affect the outcome (the results are useful to improve the

methodology and tool); and (iii) the probabilistic framework provides a straightforward way to integrate geotechnical assessment tools into existing probabilistic seismic hazard methods as well as decision-support tools for implementing earthquake risk mitigation measures (Fig. 3).

Step-by-Step Methodology

The steps are:

- Estimation of peak ground acceleration (PGA) at building/bridge site:** The assessment of D_L requires (i) estimation of ground motion parameters (typically, peak ground acceleration (PGA)) at a building site due to a specified scenario and (ii) assessment of liquefaction initiation potential at different depths along the pile length. Equation 2 is a typical equation to obtain PGA.

$$\text{Log } PGA_{\text{bldg}} = f(M_w, R_{\text{bldg}}, V_{S30, \text{bldg}}) + \varepsilon_{\text{bldg}} \quad (2)$$

where PGA_{bldg} is PGA value at the building site, M_w is the moment magnitude, R is the distance measured (typically closest distance to fault rupture plane), V_{S30} is the average shear-wave velocity in the uppermost 30 m in (m/s), and $\varepsilon_{\text{bldg}}$ is the random error that is

Safety Assessment of Piled Buildings in Liquefiable Soils: Mathematical Tools, Fig. 3 Schematic diagram showing the methodology

modeled as a normal variable with zero mean and logarithmic standard deviation.

(b) **Assessment of the depth of liquefiable soil:**

The next step is to conduct probabilistic liquefaction potential evaluation of a soil column (along a pile) at the building site to estimate D_L for a given seismic excitation level. Such assessment is often conducted by using simplified stress-based methods of Seed and Idriss (1971) based on standard penetration test (SPT) data, cone penetration test (CPT) data, and shear-wave velocity (V_S) data. Recently, probabilistic procedures for liquefaction initiation have been developed by considering different in situ measures for describing soil strength. Using a sophisticated Bayesian regression analysis and well-screened case

studies, Cetin et al. (2002, 2004) developed a statistical model for calculating the probability of liquefaction initiation based on SPT data, while Moss et al. (2006) developed a counterpart using CPT data. Using the first-order reliability method, Juang et al. (2005) developed a similar model based on V_S data. The significance of these developed models is that key uncertainties associated with the input data/parameters and the adopted models themselves are taken into account; the developed models can produce unbiased potential of liquefaction initiation and are useful to conduct probabilistic liquefaction hazard analysis (Goda et al. 2011). The probability of liquefaction initiation P_L at a depth of interest can be estimated as

$$P_L = \Phi \left(-\frac{N_{1,60}(1 + 0.004FC) - 13.32\ln(CSR_{eq}) - 29.53\ln(M_w) - 3.70\ln(\sigma'_v/P_a) + 0.05FC + 16.85}{2.7} \right) \quad (3)$$

where Φ is the standard normal function, $N_{1,60}$ is the corrected SPT counts (but not

adjusted for fines content), FC is the fines content (in percentage), CSR_{eq} is the cyclic

**Safety Assessment of
Piled Buildings in
Liquefiable Soils:
Mathematical Tools,**

Fig. 4 Depth required for fixity a pile

stress ratio (but not adjusted for the moment magnitude), and σ'_v is the vertical effective stress.

- (c) **Unsupported length of the pile (D_L):** The next step is to determine the unsupported pile length (D_L) based on the liquefaction profile. D_L is equal to the thickness of liquefied soil layers plus some additional length necessary for fixity at the bottom of the liquefied soils. Typical calculations show that the fixity depth is about three to five times the diameter of the pile (see Fig. 4); see Bhattacharya and Goda (2013). If a relatively thin non-liquefied layer is overlain and underlain by thick liquefied layers, lateral restraint of the pile at the non-liquefied layer might not be expected, i.e., the pile is unsupported. In such a case, the thin non-liquefied layer can be ignored in determining D_L , and the unsupported length needs to be extended until a thick non-liquefied layer is encountered. However, if there is a complex soil profile with alternating liquefiable and non-liquefiable soil layers, more detailed analysis is required.
- (d) **Assessment of the critical pile length H_C :** This section describes the mathematical background behind the rationale of obtaining the critical pile depth H_C . Before the onset of shaking, the static axial load P_{static} acts on

each pile beneath a building, assuming that each pile is equally loaded during static condition and neglecting any eccentricity of loading. During an earthquake, inertial action of the superstructure imposes the dynamic axial load on the piles, which will increase the axial load on some piles. These piles with increased axial loads may be vulnerable to buckling. An estimate of the maximum axial compressive load acting on a pile can be given by

$$P_{dynamic} = (1 + \alpha)P_{static} \quad (4)$$

where α is termed as the dynamic axial load factor and is a function of type of superstructure, height of the center of mass of the superstructure, and characteristics of the earthquake shaking (e.g., frequency content and amplitude).

For buckling instability analysis, each pile needs to be evaluated with respect to its end conditions, i.e., fixed, pinned, or free. Each pile in a group of identical piles will have the same buckling resistance as a single pile. If a group of piles is fixed in a stiff pile cap and embedded sufficiently at the tip, as in Fig. 2, the pile group will buckle in side sway.

The elastic critical load of a single pile, P_{cr} , can be estimated as

Safety Assessment of Piled Buildings in Liquefiable Soils: Mathematical Tools, Table 1 Values of K in Eq. 7

Boundary condition of the pile at the top and bottom of the liquefied layer		Effective length	K	Examples
Top	Bottom			
Fixed	Fixed [sufficient embedment at the dense layer]	$L_{\text{eff}} = 0.5H_c$	0.5	Pile groups with raked piles
Free to translate but restrained against rotation – sway frame	Pinned [insufficient embedment at the dense layer]	$L_{\text{eff}} = 2H_c$	2	See, for example, NFCH (Niigata Family Court House) building in Bhattacharya (2003)
Free to translate but restrained against rotation – sway frame	Fixed [sufficient embedment at the dense layer]	$L_{\text{eff}} = H_c$	1	Most cases fall under such category; see, for example, Fig. 2
Fixed in direction but free to rotate	Fixed [sufficient embedment at the dense layer]	$L_{\text{eff}} = 0.7H_c$	0.7	Pile groups with raked piles. Improper pile-pile cap connection
Fixed in direction but free to rotate	Pinned [less embedment at the dense layer]	$L_{\text{eff}} = H_c$	1	Pile groups with raked piles. Improper pile-pile cap connection
Free, i.e., unrestrained against rotation and displacement	Fixed [sufficient embedment at the dense layer]	$L_{\text{eff}} = 2H_c$	2	Piles in a row such as the Showa Bridge piles

$$P_{cr} = \frac{\pi^2 EI}{(L_{\text{eff}})^2} \quad (4)$$

where L_{eff} is the effective length, i.e., Euler's equivalent buckling length of a strut pinned at both ends, and EI is the bending stiffness of the pile. The effective length of the pile (L_{eff}) can be found in Table 1 or from any structural mechanics textbook or codes of practice. The unsupported length of the pile D_L is equal to the thickness of liquefiable soil plus some additional length necessary for fixity at the bottom of the liquefiable soil.

The applicability of the elastic critical load, as in Eq. 4, to pile buckling failure is an important factor. Experiments show that the actual failure load of a slender column is much lower than that predicted by Eq. 4. Rankine (1866) recognized that the actual failure involves an interaction between elastic and plastic modes of failure. Lateral loads and inevitable geometrical imperfection lead to creation of bending moments in addition to axial loads. Bending moments have to be accompanied by stress resultants that diminish the cross-sectional area available for carrying the axial load; thus the actual failure load is likely to be less than the elastic critical load,

i.e., $P_{\text{failure}} < P_{cr}$. Equally, the growth of plastic bending zones reduces the effective elastic modulus of the section, thereby resulting in the decreased critical load for buckling (i.e., capacity). Furthermore, these processes feed each other, and as elastic critical loads are approached, all bending effects are magnified. Stability analysis of elastic columns showed that if lateral loads in the absence of axial load would create a maximum lateral displacement δ_0 in the critical mode shape of buckling, then the displacement δ under the same lateral loads but with the concurrent axial load P is given by

$$\frac{\delta}{\delta_0} = \frac{1}{1 - P/P_{cr}} \quad (5)$$

The term δ/δ_0 is the buckling amplification factor (i.e., amplification of lateral displacement due to the presence of the axial load). Figure 5 presents a graph of the buckling amplification factor plotted against the normalized axial load P/P_{cr} , where P denotes the applied axial load. It can be observed from Fig. 5 and Eq. 6 that if the applied load is 50 % of P_{cr} , the amplification of lateral deflection due to lateral loads is about two times. At these large deflections, secondary moments

Safety Assessment of Piled Buildings in Liquefiable Soils: Mathematical Tools,

Fig. 5 Buckling amplification factor versus normalized axial load

will be generated due to P - Δ moment, leading to more deflection. It is therefore important to remain in the linear regime and not in anyway near the asymptotic region, where the buckling amplification factor increases dramatically (e.g., $P/P_{cr} > 0.6$).

Moreover, it would also be unwise to use a factor of safety less than three against the Euler load of a pile, i.e., ($P/P_{cr} = 0.33$). Such consideration is consistent with general design practice where structural engineers use a factor of safety of at least three against linear elastic buckling to take into account the eccentricity of load, deterioration of elastic stiffness due to plastic yielding, and unavoidable imperfection. The actual failure load $P_{failure}$ is therefore some factor ϕ ($\phi < 1$) times the theoretical Euler's buckling load given by Eq. 5.

$$P_{failure} = \phi P_{cr} \quad (6)$$

Based on the above discussion, it may be inferred that buckling instability is initiated at around 0.35, i.e., $\phi = 0.35$. It is noted that in reality, this factor depends on the axial load, imperfection of piles, and residual stress in the pile due to driving. The selection of ϕ is one of the significant sources of uncertainty in determining the critical pile depth H_C .

Determination of "Critical Depth" H_C

In the limit state condition of failure, $P_{dynamic} = P_{failure}$. For the type of structure shown in Fig. 2, $L_{eff} = H_C$ in Eq. 4. In order to generalize the boundary condition of the pile (i.e., pile head fixity condition with pile cap/superstructure and the fixity at the interface between liquefiable and non-liquefiable layers at deeper depths), one may write Eq. 7:

$$L_{eff} = K \times H_C \quad (7)$$

where K is the column effective length factor (e.g., $K = 1$ for free lateral translation but restrained against rotation-sway motion). Values of K for other boundary conditions of the pile are given in Table 1.

With the abovementioned assumptions, Eq. 6 can be rewritten as

$$P_{dynamic} = \phi P_{cr} = \frac{\phi \pi^2 EI}{K^2 H_C^2} \quad (8)$$

Rearranging Eq. 8 gives the estimate of the critical depth H_C for a pile as follows:

$$H_C = \sqrt{\frac{\phi \pi^2 EI}{K^2 P_{dynamic}}} = \sqrt{\frac{\phi \pi^2 EI}{K^2 (1 + \alpha) P_{static}}} \quad (9)$$

Safety Assessment of Piled Buildings in Liquefiable Soils: Mathematical Tools, Fig. 6 Loading condition of pile foundation in pre-liquefaction and post-liquefaction stages

Therefore, the assessment of H_C is based on the calculation of the critical buckling load for a pile foundation surrounded by liquefied soils (from which the pile cannot receive sufficient lateral support). Key parameters in Eq. 9 are ϕ , K , and α . Reasonable values of ϕ and K can be selected based on engineering judgment.

Based on the procedure described above, both D_L and H_C can be assessed probabilistically. The occurrence of pile foundation failure due to buckling mechanism is indicated if $H_C < D_L$. By sampling D_L and H_C many times, probabilistic assessment of liquefaction-induced pile foundation failure due to buckling mechanism can be carried out.

Formulation for Determination of Dynamic Load Amplification Factor (α)

One of the critical factors is the assessment of α . This can be facilitated by examining axial forces acting on a pile in pre-liquefaction and post-liquefaction situations as shown in Fig. 6. In a pre-liquefaction stage, the plane of fixity of a building with pile foundation surrounded by non-liquefied soils can be estimated by following a similar procedure as shown in Fig. 4, i.e., depth from ground surface to the plane of fixity is denoted by D_{fix} in Fig. 6 and is typically a few meters. By assuming that the natural vibration period of the building before liquefaction is T_{pre} ,

the maximum axial force acting on a pile due to inertia can be calculated as

$$P_{pre} = \frac{\beta_1 (W/g) \times SA(T_{pre}, \xi_{pre}) \times (D_{fix} + \beta_2 H_B)}{(N_p/2) \times B} \quad (10)$$

where W is the total weight of a building (note: $W = P_{static} N_p$), $SA(T_{pre}, \xi_{pre})$ (g) is the spectral acceleration at T_{pre} with damping ratio ξ_{pre} (typically, 2–5 %), β_1 is the coefficient to account for modal mass for the fundamental vibration mode (typically, 0.8–0.9), β_2 is the coefficient to account for the effective height where the inertia due to the modal mass acts (typically, 0.65–0.75), H_B is the height of building, N_p is the number of piles (assuming that an equal number of piles are positioned in two rows), and B (m) is the foundation width between the two rows of piles (note: the foundation width B is along the direction where axial force is induced by overturning moment due to lateral inertia). T_{pre} can be estimated by using an empirical equation, such as $T_{pre} = 0.09 H_B / B^{0.5}$; see Anderson et al. (1952) also adopted in IS 1893.

In a post-liquefaction situation, the building is supported by piles that have relatively long unsupported lengths of D_L (as evaluated based on the liquefaction initiation analysis). In this

case, the natural vibration period in a post-liquefaction stage, T_{post} , can be calculated as

$$T_{\text{post}} = 2\pi \sqrt{\frac{W/g}{N_p \times 12EI/D_L^3}} \quad (11)$$

where $12EI/(D_L)^3$ is the lateral stiffness of each pile. Then, the maximum axial force acting on a pile is given by

$$P_{\text{post}} = \frac{(W/g) \times SA(T_{\text{post}}, \xi_{\text{post}}) \times (D_L + \beta_3 H_B)}{(N_p/2) \times B} \quad (12)$$

where $SA(T_{\text{post}}, \xi_{\text{post}})$ (g) is the spectral acceleration at T_{post} with damping ratio ξ_{post} (typically, 10–30 % representing the damping of liquefied soil) and β_3 is the coefficient to account for the effective height where the inertia acts in a post-liquefaction condition (typically, 0.5). The underlying assumption of Eqs. 11 and 12 is that the building is considered as a rigid mass and the pile provides the primary lateral stiffness to the building. It must be mentioned that this approach is very simple, and many uncertainties, such as effects of vertical inertia, timing of max inertia and timing of loss of lateral support due to liquefaction, and potential effects due to lateral spreading, are not taken into consideration.

By defining $\alpha = \max(P_{\text{pre}}/P_{\text{static}}, P_{\text{post}}/P_{\text{static}})$, α is given by:

$$\alpha = \frac{2}{gB} \max[\beta_1 SA(T_{\text{pre}}, \xi_{\text{pre}})(D_{\text{fix}} + \beta_2 H_B), SA(T_{\text{post}}, \xi_{\text{post}})(D_L + \beta_3 H_B)] \quad (13)$$

The additional information needed for evaluating α is the estimated spectral acceleration values at vibration periods T_{pre} and T_{post} with damping ratios ξ_{pre} and ξ_{post} (note: T_{pre} and T_{post} are random variables; in particular, T_{post} is significantly affected by liquefaction initiation analysis).

A case study: collapse of a 5-story RCC building in Kobe during the 1995 Kobe earthquake:

Several buildings with pile foundation had to be demolished due to severe liquefaction damage during the 1995 M_w 6.9 Kobe earthquake. Because of the dramatic consequences, several detailed post-earthquake investigations were conducted to examine the cause and failure mechanism of these cases (Tokimatsu et al. 1997). For illustration, one of such case studies (Uzuoka et al. 2002; Bhattacharya 2006) is focused upon. A 5-story reinforced concrete frame building (total height $H_B = 14.5$ m) was located at 6 m from the quay wall on a reclaimed fill in the Higashinada area of the Kobe City; the distance from the rupture plane to the building site was about 5 km (Fig. 7). The Kobe earthquake caused a lateral displacement of 2 m to the quay wall toward the sea, and the building was tilted by 3° due to lateral spreading. The schematics of the post-earthquake investigation of the building and pile foundation are shown in Fig. 8. At the building site, significant lateral spreading was observed (about 1.0–1.5 deformation/movement of the ground toward the sea; Tokimatsu et al. 1997).

The building was supported on 38 hollow pre-stressed concrete piles (there were two pile rows separated by 7.5 m and 19 piles were aligned in each row); the pile length was 20 m with exterior and interior diameters of 0.4 and 0.24 m, respectively. Figure 9 shows variations of soil profiles and SPT N counts with depth at the building site. The site has fill/sand layers with relatively low N counts (e.g., 2–9 m and 12–16 m), which are susceptible to liquefaction (i.e., saturated sand layers with low strength); the average shear-wave velocities in the uppermost 12 and 30 m are estimated to be about 147 and 216 m/s, respectively. The water table level was about 2 m below ground surface. The post-earthquake investigation by Tokimatsu et al. (1997) indicated that soil layers shallower than 9 m were liquefied (based on a simplified stress method). Moreover, the borehole logging data shown in Fig. 8 suggest that the sandy silt

Safety Assessment of Piled Buildings in Liquefiable Soils: Mathematical Tools, Fig. 7 Location of the building site and observation site

layer between 12 m and 16 m, having low strength, may be disturbed by strong ground motion; thus this layer may not offer much fixity to the pile.

The nearby ground motion recording was obtained at the Higashi Kobe Bridge, which is away about 0.9 km from the building site; distance to the rupture plane for the observation and building sites is about 5.2 and 4.4 km, respectively. The site condition at the observation site is similar to that at the building site (typically, NEHRP site class D or E). The recorded acceleration time histories at the observation site are shown in Fig. 9 (Public Works Research Institute 1995).

The 5 % damped response spectra of the two horizontal components and their geometric mean are presented in Fig. 9 and are compared with the median GMPE (Ground Motion Prediction Equations) by Zhao et al. (2006); this relation is used as a representative regional model throughout this study to estimate ground motion parameters at the building site. The comparison of the calculated response spectra with the Zhao et al. relation indicates that the observed response spectra have less spectral content at vibration periods less than 1.0 s, while they contain rich spectral content at vibration periods greater than 1.0 s. The responses at short vibration periods are likely

to be affected by nonlinear site amplification (i.e., de-amplification), and at such a site, liquefaction-induced ground failure may be expected. Further to note, geographical positions of the fault plane,

hypocenter, and the observation site (Fig. 6) are of typical “near-fault motions” due to forward directivity (Mavroeidis and Papageorgiou 2003); this can be corroborated by large response spectra

Fig. 11 Comparison of probability mass functions for D_L and H_C

Summary

A probabilistic-based method to reassess such safety has been formulated in this entry. This method can easily be coded in a program, such as MATLAB or Fortran. This method checks the stability of the foundation against buckling instability at full liquefaction, i.e., when the soil surrounding the pile is at its lowest possible stiffness. Two parameters, namely, “critical depth of the pile H_C ” and the “unsupported length of the pile due to liquefaction D_L ,” are estimated. Critical depth is a function of axial load acting on the pile (P), flexural stiffness of the pile (EI), and the boundary condition of the pile above and below the liquefiable soil. On the other hand, D_L mainly depends on the earthquake characteristics, soil profile, and ground conditions. A case study is considered to illustrate an application of the methodology.

SAR Images, Interpretation of

Antonio Iodice and Daniele Riccio

Dipartimento di Ingegneria Elettrica e delle Tecnologie dell'Informazione, Università degli Studi di Napoli Federico II, Napoli, Italy

Introduction

A synthetic aperture radar (SAR) is a remote sensing microwave imaging system which consists of a radar sensor mounted on a moving platform, such as an airplane or a satellite. As the platform flies along an approximately straight line, the radar emits microwave pulses at fixed rate (pulse repetition frequency (PRF)) and receives corresponding returns (echoes) backscattered by the illuminated scene. A SAR is able to distinguish points at different distances from the line of flight based on different delays of their returns; in addition, points at different positions along a direction parallel to the line of flight are distinguished by forming a very long (and therefore very directive, with a very narrow beam) synthetic array. This is obtained by properly combining pulses received by the sensor at different positions along the line of flight, so that the synthetic array length is equal to the length of the portion of line of flight such that a given ground point remains within the real antenna beamwidth. In this way, a two-dimensional (2D) image is obtained, which is the projection

of the scene onto the plane containing the look direction (range direction) and the line of flight (azimuth direction). This is at variance with optical images, which are the projection of the scene onto the plane perpendicular to the look direction.

A SAR is an active sensor (i.e., it illuminates the scene), so that it can work during both the day and the night; in addition, it relies on microwaves, which can propagate through clouds, so that it can image the Earth's surface even in the presence of a cloud cover.

An important parameter characterizing an imaging sensor is its resolution, which is the minimum distance between two points such that they can be distinguished by the sensor. For a SAR sensor, the resolution along the range direction is $c/(2B)$, where c is the speed of light and B is the pulse bandwidth, whereas the resolution along the azimuth dimension is $\lambda r/(2X)$, where λ is the electromagnetic wavelength, r is the sensor-to-ground distance, and X is the synthetic array length. In its usual acquisition mode ("strip map" mode), the SAR radar antenna is constantly pointed along a direction perpendicular to the line of flight, forming a significant angle ("look angle") with the nadir direction (i.e., SAR is a "side looking" sensor); see Fig. 1. In this case, the synthetic antenna length X is $\lambda r/L$, where L is the real antenna effective azimuth length, so that the azimuth resolution turns out to be $L/2$. Note that the SAR resolution is independent of the

sensor-to-scene distance, at variance with the one of optical sensors. In order to obtain a higher (better) resolution, although with a smaller illuminated scene, a "spotlight" acquisition mode can be used, in which the SAR antenna beam is steered during the flight to constantly illuminate a given spot on the ground. In this way, a longer synthetic array can be obtained, this implying a better azimuth resolution. The resolution of modern spaceborne SAR systems spans from about 10 m to fractions of meter.

A SAR image provides information on the imaged scene which is in some sense complementary with respect to that provided by an optical image. In fact, while the intensity of a pixel in an optical image mainly depends on the chemical properties of the surface of the imaged objects, the intensity of a pixel in a SAR image depends on electromagnetic properties (permittivity and conductivity) of imaged objects and on their roughness at wavelength (i.e., centimetric) scale: smooth surfaces (calm water, concrete or asphalt surfaces, etc.) appear as dark areas on the image, whereas surfaces with increasing roughness appear as increasingly bright areas.

Finally, another important peculiarity of SAR sensors with respect to optical ones is their "coherent" nature: in fact, they are able to emit a coherent radiation and to measure not only the intensity of the received signal but also its phase. This allows using interferometric techniques (interferometric SAR (InSAR) and differential interferometric SAR (DInSAR)) to obtain terrain topography and to monitor small terrain movements and tomographic techniques (SAR Tomography) for the three-dimensional reconstruction of imaged objects. In addition, using two orthogonally polarized transmitting and/or receiving antennas, information can be extracted by observing how the polarization of the backscattered wave is modified with respect to the transmitted one (SAR Polarimetry). However, the coherent nature of SAR also causes the appearance of the "speckle" noise, which gives a "salt-and-pepper" look to SAR images: a macroscopically homogeneous area appears to be composed of pixels of randomly varying intensity. Speckle noise can be reduced, at the expense of

SAR Images, Interpretation of, Fig. 1 Geometry of SAR acquisition

SAR Images, Interpretation of,

Fig. 2 Geometric distortions. Foreshortening-compression ($A'B'$), foreshortening-dilation ($B'C'$), layover ($E'D'$), shadow ($D'-G'$)

geometric resolution, by averaging over adjacent pixels (multi-look image), or by proper filtering.

By summarizing, SAR sensors have significant advantages with respect to optical ones (day-and-night, all-weather capabilities, coherent nature), but SAR images are more difficult to be visually interpreted than optical ones, due to both geometrical (i.e., image projection plane including the look direction) and radiometric (i.e., involved dependence of image intensity on terrain electromagnetic and roughness properties, speckle) issues. Fundamentals on SAR systems and applications can be found, e.g., in Ulaby et al. (1986), Elachi (1988), and Curlander and McDonough (1991). ▶ [InSAR](#) and ▶ [SAR Tomography](#) are the subjects of other entries of this encyclopedia, whereas SAR Polarimetry is analyzed in detail in Lee and Pottier (2009).

Foreshortening, Layover, Shadow, and Geocoding

Due to the fact that a SAR image is the projection of the scene onto a plane including the look direction, geometric distortions on SAR images are very different from those experienced in optical images.

If terrain slope is smaller than the look angle θ , the resolution cell on the ground is compressed with respect to the horizontal terrain case if the surface is tilted toward the sensor; otherwise it is dilated (see Fig. 2.). This effect is termed “foreshortening.”

If the surface is tilted toward the sensor and its slope is larger than the look angle, then there is an “inversion” of the SAR geometry: the positions along the range direction of peaks and bases of hills or mountains are exchanged, and the sides of hills or mountains are “folded” onto the valleys in front of them (so that a single pixel corresponds to both an area on the hill’s side and an area on the valley, and a very bright area on the image appears) (see Figs. 2 and 3). This effect is called “layover.”

Finally, if the surface is tilted away from the sensor and its slope is larger than 90° minus the look angle, then a portion of the surface is not illuminated (see Fig. 2), and no return is present in that portion of the SAR image: a “shadow” appears.

If SAR platform trajectory and terrain topography are known, abovementioned geometric distortions can be mitigated by a post-processing step, called “geocoding,” that allows representing the SAR images in a standard cartographic map projection. In this way, the image can be, for instance, easily integrated in a GIS. Note however that, although foreshortening can be corrected by geocoding, layover and shadow effects imply a loss of information that cannot be recovered by this post-processing step. In addition, geocoding implies an interpolation process that may alter the image information content: therefore, in some applications it may be preferable to extract the physical parameter of interest directly from the image in SAR native geometry and then to geocode the obtained final

SAR Images, Interpretation of, Fig. 3 COSMO/SkyMed SAR image of the area of Mt. Vesuvius, Italy (*left*). Near range is on the left. Geocoded version of the

same image (*right*). The very bright area near the crater corresponds to a layover area

SAR Images, Interpretation of, Fig. 4 Elements on a building facade forming dihedral and trihedral structures

map (Guida et al. 2008; Di Martino et al. 2012). An example of SAR image before and after geocoding is shown in Fig. 3.

Interpreting SAR Images of Buildings

Geometric distortions described in the previous section are particularly severe in SAR images of urban areas, which are of prominent interest if, for instance, a fast post-event earthquake damage assessment is needed. With the launch of COSMO/SkyMed and TerraSAR-X missions,

very-high-resolution (VHR) SAR images of urban areas have become routinely available. In particular, in the spotlight acquisition mode, COSMO/SkyMed SAR sensors are able to obtain a resolution even better than 1 m. Accordingly, in principle a lot of information on objects present in the urban scenario can be extracted from such images; however, due to the above-cited severe geometric distortions and due to the involved interaction between incident electromagnetic wave and imaged scene, direct interpretation of VHR SAR images is not straightforward. It is easy to realize (see Figs. 4 and 5) that such

SAR Images, Interpretation of, Fig. 5 SAR image formation for a single building

images are dominated by the combination of single scattering from terrain and buildings and multiple scattering from dihedral and trihedral structures. For moderate- and low-resolution systems, they may be simultaneously present in a single resolution cell. Nonetheless, for very-high-resolution SAR systems, the resolution cell is so small that dihedral and trihedral returns dominate with respect to the single scattering background. Accordingly, a realistic description of VHR SAR amplitude images can be obtained by considering sparse brilliant points, or lines, over a dark background: the positions of these brilliant points and lines can be considered randomly distributed, unless they belong to a building facade, in which case an ordered, periodic spatial distribution is expected.

In fact, if we consider a single building, as illustrated in Fig. 5, by moving from near to far range, we first find a layover area in which each pixel is the superposition of two or three contributions: one from the ground, one from the vertical wall, and possibly one from the roof. Ground and roof are usually so smooth that corresponding contributions are weak, whereas often, on the vertical walls, dihedral or trihedral structures of balconies and windows are present (see Fig. 4) whose contributions to the backscattered signal are significant. In fact, with regard to dihedral structures, it is easy to realize that, if the structure is aligned with the SAR line of flight, all double-

bounce paths have the same length, corresponding to twice the path length from the sensor to the internal edge of the dihedral, and hence they reach the sensor simultaneously. Accordingly, a very bright line appears on the image. Similarly, if we consider a trihedral structure, for a wide range of structure orientations, all triple-bounce paths have the same length, corresponding to twice the path length from the sensor to the internal corner of the trihedral, and hence they reach the sensor simultaneously. Accordingly, a very bright point appears on the image. Since balconies and windows usually are spatially distributed in an ordered way, they form periodic patterns of brilliant lines and/or points within the layover area of the SAR image of the building.

By continuing to move from near to far range, the end of the layover area is marked by a bright line representing the double-bounce return from the large dihedral structure formed by the vertical wall and the ground. This line is particularly evident if the wall is aligned with the sensor line of flight. Then, a dark area is present, including the very weak triple-bounce return (wall-ground-wall and/or ground-wall-ground) and, possibly, the weak return from the roof. And, finally, we find a very dark shadow area.

An example of VHR SAR image of an urban area is reported in Fig. 6a. This is a 1-m resolution TerraSAR-X image of Naples, Italy. Near range

SAR Images, Interpretation of, Fig. 6 TerraSAR-X image of Naples, Italy (a). Near range is on the left. Excerpt of the previous image showing the area of Piazza del Plebiscito (b). An optical image of the same area (c)

is on the left. In Fig. 6b an excerpt of the previous image is reported, and in Fig. 6c an optical image of the same area is shown. The square at the center of this area is Piazza del Plebiscito, and the building at its right side is the Palazzo Reale (Royal Palace). In agreement with our previous discussion, in correspondence of the façade of

this building, by moving from left to right (i.e., from near to far range), we can distinguish three bright lines, followed by a very bright line and by a dark area. The three bright lines correspond to an architectural structure at the roof edge and to two lines of balconies, whereas the very bright line corresponds to the wall-ground

double-bounce return. Finally, the dark area corresponds to building roof and shadow.

Model-Based Interpretation of SAR Images

Above presented description allows a qualitative interpretation of SAR images of natural and urban areas. Quantitative information on the geometry (i.e., distances between objects, building size, floors' height, etc.) can be also obtained from such an analysis if look angle and pixel spacing are known. However, in order to obtain quantitative relations between image intensity and scene properties, a deeper analysis is needed. First of all, the scene must be described in terms of parameters of interest: for instance, for a natural scenario, soil moisture and composition, terrain roughness, vegetation biomass, etc. Then, a direct electromagnetic scattering model must be used to express the backscattered field in terms of such scene parameters. Inversion of this model allows retrieving the scene parameters of interest from SAR images of the scene.

This field is currently the subject of intense research activity, and the description of scattering models and retrieval algorithms goes beyond the scope of the present work. However, a review of scattering models can be found in some textbooks (e.g., Ulaby et al. 1986; Tsang et al. 2000; Franceschetti and Riccio 2007) and scientific papers (e.g., Fung et al. 1992; Franceschetti et al. 2002). Examples of retrieval algorithms can also be found in the scientific literature, both for natural scenes (Iodice et al. 2011; Di Martino et al. 2012) and urban areas (Guida et al. 2008, 2010).

RGB Compositions

Visual interpretation of SAR images can be made easier by combining different SAR images of the same area to create a false color image.

For instance, if a SAR polarimetric system is employed, a combination of different polarimetric channels can be used. Available channels are

HH (i.e., transmit a horizontally polarized electromagnetic field and measure the horizontally polarized component of the received field), VV (i.e., transmit a vertically polarized electromagnetic field and measure the vertically polarized component of the received field), and HV or VH (i.e., transmit a horizontally polarized electromagnetic field and measure the vertically polarized component of the received field, or vice versa). For a wide range of scattering surfaces (reciprocal scatterers), HV and VH channel returns are equal, so that only one of the two can be actually used. A very useful combination consists of HH + VV, HH-VV, and HV channels, and it is called a "Pauli decomposition" (Lee and Pottier 2009). In fact, it turns out that the sum of HH and VV returns is dominated by single scattering from rough surfaces (soil surfaces, sea surfaces), the difference of HH and VV returns is dominated by double scattering (terrain-building walls, or ground-tree trunks), and HV return is dominated by volumetric scattering or extremely rough surface scattering (vegetation). Accordingly, an RGB color image can be obtained by loading the HH + VV signal onto the blue channel, HH-VV onto the red channel, and HV onto the green one. Accordingly, blue areas on the image will correspond to bare or little vegetated soils, or sea; red areas to built-up areas or trees with little foliage; and green areas to very vegetated soils or forests. Intermediate colors will correspond to pixels containing combinations of the previous targets. An example of false color SAR image obtained by using the Pauli decomposition is reported in Fig. 7.

Another possibility is to load, onto the three different color channels, SAR images of the same area acquired at different times. This allows to easily identify areas subjected to changes between two different acquisitions. For instance, in Fig. 8 a false color SAR image of an area in a semiarid region (Tougou basin, Burkina Faso) is shown. An image acquired during the dry season is loaded onto the blue channel, another image acquired in the wet season is loaded onto the green channel, and the interferometric coherence between the two acquisitions (see ► [InSAR and](#)

SAR Images, Interpretation of, Fig. 7 False color image obtained by performing a Pauli decomposition on the polarimetric SAR image of an agricultural area

SAR Images, Interpretation of, Fig. 8 False color SAR image of the Tougou basin area (Burkina Faso)

A-InSAR: Theory is loaded onto the red channel. Accordingly, different colors can be interpreted as follows (Amitrano et al. 2015):

Black areas: permanent basin water (dark on both images, low coherence)

Blue areas: wet season basin water (dark on wet season image, intermediate on dry season image, low coherence)

Green areas: wet season vegetation (bright on wet season image, intermediate on dry season image, low coherence)

Red or white areas: man-made objects, village (intermediate or bright on both acquisitions, high coherence)

Blue-green intermediate color, high intensity (cyan): trees (bright on both acquisitions, low coherence)

Blue-green intermediate color, intermediate intensity (Prussian blue or dark green): bare soils (intermediate on both acquisitions, intermediate coherence)

Note that the one described above is just an example: different RGB compositions can be employed, according to the considered application and to the scene characteristics that the user is interested to highlight.

Summary

SAR sensors have significant advantages with respect to optical ones: day-and-night, all-weather capabilities, and the possibility of measuring terrain topography and monitoring small terrain movements, due to its coherent nature. In addition, SAR images of virtually any area of the Earth surface are today routinely available, due to the different SAR satellite missions currently in orbit. Therefore, their use has a huge potential impact on a number of applications, among which the fast post-event earthquake damage assessment.

However, visual interpretation of SAR images by a human operator requires that the latter is properly trained to get used to the peculiar characteristics of SAR images: geometric distortions, involved dependence of image intensity on terrain electromagnetic and roughness properties, and speckle noise. Visual interpretation can be made easier by properly combining different images to form a color image (RGB composition).

Finally, automatic quantitative interpretation of SAR images requires the availability or the development of electromagnetic scattering models and of corresponding retrieval algorithms. This field is currently the subject of an intensive research activity.

Introduction

Synthetic-aperture radar (SAR) is one of the most important Earth remote sensing sensors whose applications have grown dramatically in the recent years. It provides images at microwaves with resolution comparable to that of optical systems, but with the crucial advantage of all-time, day/night, and all-weather, imaging capability. Similarly to classical surveillance radars, SAR measures the distance (range) from sensor to target: resolutions of the order of meters are achieved through the pulse compression of large bandwidth (frequency-modulated) signals. Very high resolution in the along-track direction is achieved as well through the coherent combination of target echoes received over the illumination interval, thus implementing a virtual (synthetic) array of antennas (i.e., a very large antenna) by exploiting the movement of a very small antenna mounted on board airplanes or satellites. The latter feature turns SAR systems to be imaging radars.

SAR data are nowadays used in many areas of environmental risks monitoring situations such as flooding, glaciers, land cover, and forest monitoring (Curlander and McDonough 1991; Moreira et al. 2013). Among all, one of the primary applications of SAR is the 3D reconstruction and monitoring of the Earth surface displacements through the use of interferometric techniques.

SAR interferometry (InSAR) exploits the coherent properties of the sensor, i.e., the capability to accurately control not only the envelope but also the phase of the transmitted radiation. SAR images are in fact complex data characterized by an amplitude measurement (envelope), related to the backscattering properties of the scene, as well as a phase signal related to both phase of the backscattering coefficient and to the distance of the target from the sensor to an accuracy of the order of the wavelength (centimeters at microwaves). Similarly to the human vision system, acquiring images with a slight angular diversity allows SAR to be sensitive to the 3D scene properties, i.e., to estimate the topography of the observed scene. Topography is not accessible in a single SAR acquisition because the

imaging process returns only a 2D projection of the 3D reality. The Shuttle Radar Topography Mission (SRTM) in the last decade has represented the first case of an extensive use of InSAR for the generation of a worldwide (except for the poles) digital elevation model (DEM), that is, a digital topography map of the Earth surface (Van Zyl 2001). SRTM DEM (90 m spacing DTED-1 standard) has been extensively used in many applications. Nowadays, the TerraSAR-X/TanDEM-X mission (launched in 2007 and 2011) is providing a “refreshing” with higher resolution (12 m spacing DTED 3 standard) of the Earth DEM on a global scale by exploiting the simultaneous acquisitions of two twin SAR sensors flying in a close formation (Krieger et al. 2007). On the other hand, differential interferometry (DInSAR) takes advantage of the very high precision of radar systems in measuring phase to estimate differential displacements of the area imaged at different time instants with an accuracy of the order of a fraction of the used wavelength. DInSAR is today routinely used to estimate displacements induced by large earthquakes as well as to monitor volcanic activities producing ground movements, subsidence caused by water and/or oil extraction, mining activities, and also slow moving landslides (Massonnet et al. 1993; Carnec et al. 1995; Fornaro and Franceschetti 1999; Crosetto et al. 2005).

The availability of long-term data archives of former C-Band ESA ERS1/2 and ENVISAT SAR satellites has pushed the development of multipass interferometric processing techniques which coherently process large dataset of tens of images. In this way intrinsic limitations of classical, single pair, DInSAR, as the presence of atmospheric phase contribution and unwrapping procedures needs, affecting the unambiguous estimation of the useful deformation signal, are overcome. These techniques are mainly categorized based on the assumption on the scattering on the ground. From one hand, the approaches referred to as Persistent Scatterer Interferometry (PSI) prioritize the spatial resolution and uses all available baselines for accurate monitoring of “strong” (i.e., persistent) scatterers, typically located on anthropic structures, exhibiting

a temporal response stability over the whole observation period (Ferretti et al. 2000, 2001). On the other hand, multipass DInSAR techniques as the Small Baseline Subset (SBAS) limits the processing to interferograms characterized by short temporal separation as well as reduced angular diversity and makes use of a spatial multilooking to enhance the signal quality at the expense of a spatial resolution loss. SBAS techniques, known also as DInSAR stacking, are devoted to the monitoring of wide areas including rural zones (Berardino et al. 2002; Ferretti et al. 2011).

PSI and SBAS approaches have been used to investigate several aspects of risks for monitoring of coseismic and post-seismic deformation corresponding to several major earthquakes, volcanoes deformation, landslides, etc., as well as for the monitoring of buildings and infrastructures (Cascini et al. 2007; Arangio et al. 2013).

A recent advance for the technological viewpoint in the application to building reconstruction and monitoring is provided by SAR tomography which extends the SAR imaging concept to the third dimension of height: SAR tomography is also known as multidimensional SAR imaging technique due to the capability of full 3D imaging plus time monitoring. As for PSI, SAR tomography exploits full resolution data with angular diversity but for the use of the whole complex measured data then introducing the virtual antenna array along the height: the larger height antenna extent allows reducing again, as for the azimuth, the antenna beamwidth and reconstructing with finer resolution the backscattering along height (3D imaging) (Reigber and Moreira 2000; Gini et al. 2002; Fornaro et al. 2005). This latter allows, from one side, estimating height parameters of scatterers with better accuracy but, above all, detecting the presence of possible multiple scattering mechanisms which may interfere within the same radar spatial resolution cell. This interference, known as the layover effect, is a direct consequence of the imaging principle of radar systems which discriminates scatterers in distance: in the typical SAR side-looking geometry, in presence of steep topography, as for buildings, walls, and in

general vertical surfaces, it happens that scatterers located at different heights may be sensed by the radar at the same distance and therefore their returns imaged in the same pixel. A pictorial explanation of the layover induced on a building, as well as its effect on a very high (1 m) resolution TerraSAR-X amplitude image, is provided in Fig. 1: backscattering returns from targets located on the left part of the roof are imaged at first, and then the contributions from the facade and finally the base of the building are imaged in far range. Consequently, the building is tilted toward the sensor in the resulting SAR image: notice that because of the very high resolution, returns from the facades are spread over a large number of pixels in which contribution from ground is also expected. The vertical synthetic aperture exploited by SAR tomography allows improving resolution and tightening responses of the different interfering scatterers and then giving a chance to detect and localize separately each scattering mechanism (Fornaro and Serafino 2006). This capability has a major importance in the processing of urban areas, where the presence of buildings causes very frequent occurrence of layover between building facades, surrounding structures and ground. It is worth to note that this feature is own of the tomographic approach: none of interferometric approaches, including the PSI, can counteract this interference because of the leading assumption of only one scattering mechanism per pixel and of the phase-only signal model which does not cope with an imaging viewpoint.

As a direct extension of DInSAR, differential tomography (4D imaging) has been also proposed: it extends the 3D imaging to measure also the deformation parameters of scatterer in the focused 3D space (Lombardini 2005; Fornaro et al. 2009a; Zhu and Bamler 2010a). Along the same lines of PSI, also time series explaining the temporal evolution of deformation can be extracted, even separately for each interfering scatterers possibly exhibiting different deformation behaviors (Fornaro et al. 2009).

SAR technology is also evolved to specifically accomplish requirements and improve monitoring performances of multipass techniques.

Recent X-Band sensors as the TerraSAR-X and the Cosmo-Skymed constellation are providing images with resolution never achieved in the past, in the meter/submeter regime with reduced revisiting times. As far as the latter aspect is concerned, the Cosmo-Skymed mission is worldwide the largest constellation for civilian

application: it is composed by four small-size satellites that ensure an average revisiting time of 4 days at the maximum acquisition rate, which dramatically impacts in unexpected emergency situations when immediate imaging of damaged areas is required. High resolution allows capturing much more information from the scene,

SAR Tomography for 3D Reconstruction and Monitoring, Fig. 2 3D visualization of scatterers detected by the SAR tomography for the building imaged in the amplitude image of Fig. 1 (Reale et al. 2011a). Colors are set according to the estimated height

notably increasing the density of monitored scatterers (Gernhardt et al. 2010). At the same time, the layover becomes a major issue in the imaging of urban areas: the finer is the resolution, the larger will be the number of pixels affected by the layover induced by the buildings facades. Multidimensional imaging have demonstrated to be an effective tool in resolving the distributed layover on very high-resolution data, allowing fully separating contribution from ground and facade for the accurate 3D reconstruction of buildings. An example of the capability of multidimensional imaging for 3D building reconstruction and layover solution is provided in Fig. 2 which represents the 3D point cloud of the scatterers detected over the building imaged in Fig. 1 by the SAR tomography on a dataset of 25 TerraSAR-X very high-resolution spotlight images (Reale et al. 2011a). The precise reconstruction proves the effectiveness of this advanced processing which takes benefit of the detailed imagery provided by 1 m resolution acquisition capability.

This chapter is intended to introduce the principal concepts of the multidimensional imaging approach. A brief introduction on classical interferometric approach is firstly provided to introduce the concepts of angular and temporal

diversity in SAR imagery and their relationship with physical parameters of interest as topography and surface movements. SAR tomography is introduced as an extension which turns the interferometric processing into an imaging problem, allowing both improving performances in estimation of parameters as well as allowing extracting further information from the data with respect to interferometry as the separation and detection of interfering scatterers in layover areas. Finally, examples of the application of both multipass DInSAR (small scale), and tomographic (full resolution) processing carried out on recent Cosmo-Skymed data are provided to point out the potentiality of the joint use of these technique for a complete monitoring of risk situations at different scales, from regional up to the level of the single infrastructure, spatial scales.

The SAR Interferometry Background

SAR imaging allows discrimination of targets along the azimuth and range directions. Assuming SAR sensors to fly locally rectilinear trajectories (airborne) or orbits (spaceborne), azimuth x (directed along the sensor velocity vector) and range r (distance orthogonal from the flight track)

represent two coordinates of the natural radar cylindrical reference system with the axis coincident with the flight track. By using large bandwidths, reaching the order of hundreds of megahertz, modern sensors distinguish targets in range with a resolution degree that reaches the meter/submeter scale. In addition, a high azimuth resolution capability of the final 2D images is achieved by synthesizing antennas in the order of kilometers through the exploitation of the intrinsic motion of the platform along its orbit (Curlander and McDonough 1991).

The height information, which is not accessible in a single SAR image, can be estimated through the interferometric concept. As in any electromagnetic coherent system, the phase information is related to the traveled path and therefore to the distance of the scene from the imaging radar. Classical SAR interferometry exploits the phase difference of, at least, two images acquired with an angular diversity induced by a slight orbital offset (spatial baseline), to retrieve the 3D localization of ground scatterers. Conversely, temporal separation (temporal baseline) is exploited by the differential SAR interferometry to measure possible displacements along the radar's line-of-sight (LOS) occurring at each acquisition epoch. The winning aspect of interferometry is the very high precision of radar in the estimation of the phase values, whose accuracy is of the order of a fraction of the wavelength: this allows estimating movements with sub-centimetric accuracy, using C- and recently X-Band radars from the space. Classical DInSAR has been extensively applied to measure large deformation caused mainly from earthquakes or volcanic activities. However, the presence of additional phase disturbing contributions does not allow pushing accuracy to a millimeter accuracy through the exploitation of just few images. As stated above, the interferometric phase difference $\Delta\varphi$ of a radar system working with a wavelength λ is related to the difference δr in the traveled path of the signal forming the two images. This phase difference is composed of multiple contributions associated with different source (Fornaro and Franceschetti 1999):

$$\Delta\varphi = \frac{4\pi}{\lambda} \delta r = \frac{4\pi}{\lambda} (\delta r_z + \delta r_d) + \Delta\varphi_a + \Delta\varphi_o + \Delta\varphi_n \quad (1)$$

The first term $\delta r_z = (b/r)s$, with s being the slant height (orthogonal to the azimuth/range imaging plane corresponding to the master image) ($s = z/\sin(\vartheta)$, ϑ is the look angle), accounts for the distance variation induced by the presence of topography on the ground which plays a role in the presence of an imaging parallax measured by spatial baseline b . Conversely, δr_d is the distance variation associated with possible deformation signal (LOS component) measured among the two acquisition epochs. Subsequent terms play a disturbance role. The term $\Delta\varphi_a$ is due to the propagation delay variation between the two acquisitions induced by changes in atmosphere. Slowing produces a time delay which is mapped into a range variation. The atmospheric propagation delay (APD) exhibits a spatial correlation over hundreds of meters: it is typically on the same level of deformations which are also often spatially correlated; $\Delta\varphi_o$ and $\Delta\varphi_n$ are associated with orbital inaccuracies and noise. In applications devoted to the estimation of the scene topography, simultaneous acquisitions are preferable because both deformation and atmospheric contributions are absent: this was the case of the Shuttle Radar Topography Mission (SRTM) which employed a dual-antenna system to reconstruct the digital elevation model (DEM) of the Earth and recently of the TerraSAR-X/TanDEM-X mission which employs a pair of twin satellites flying in close formation to produce a better resolved, 12 m spatial resolution, DEM. Differently, when deformation is of interest, as in differential interferometry, repeated passes over the exactly same orbit should be required to avoid the impact of topographic phase contribution. Indeed, this requirement is problematic to enforce, and then DInSAR interferograms are produced by subtracting from the original interferogram an estimation of δr_z evaluated from an external DEM (typically the SRTM DEM): such operation, referred to as zero baseline steering (ZBS), aims at eliminating or at least mitigating the fringes corresponding to

the topography. The fringe pattern retrieved by the external DEM is usually referred to as “synthetic interferogram.” Estimation of deformation is however affected by the presence of atmospheric contribution, and then classical two-pass DInSAR configuration is usually applied to estimate predominant deformation caused, f.i., by large earthquakes.

The assumption leading to the differential phase in Eq. 1 is that the scene backscattering involved in the complex conjugate interferometric products are the same in both the images. Changes lead to the presence of noise contribution in the interferometric phase $\Delta\varphi$ which is referred to as decorrelation (Bamler and Hartl 1998; Fornaro and Franceschetti 1999). The coherence measures the degree of decorrelation: it measures the modulus of the cross-correlation index between the two images, which is a measure of the linear predictability of the two random variables corresponding to the master and slave SAR image values in the given pixel. The coherence is a product of several decorrelation effects, the most important being associated with the change of the imaging geometry due to the spatial orbit offset, the temporal separation between the acquisitions and the thermal noise. Spatial decorrelation is caused by the change of the imaging angle which determines a change of the backscattering coefficient, because of the presence in each resolution cell of a large number of scattering sources. The temporal decorrelation is due to the change of the scene backscattering properties over the time. This decorrelation source is of main importance in repeat pass interferometry, especially with systems operating at higher frequencies (f.i., X-Band). It is critical over the sea and in vegetated areas where the growth and in general the change of vegetation lead to strong variation of the backscattering coefficient. The last term, the thermal decorrelation, is due to the presence of thermal noise in the receiving apparatus. It is particularly evident in areas characterized by very low scene backscattering. Other decorrelation sources are associated with variations of the imaging aspect angle (Doppler centroid decorrelation) and to processing artifacts.

It is worth pointing out that what is really measured in interferometry is only a restricted version, corresponding to the modulus 2π of $\Delta\varphi$: one of the most critical steps of the interferometric processing is therefore represented by the unwrapping procedure which is required to retrieve the exact, unrestricted, absolute differential phase from whom quantity of interest can be estimated. Decorrelation effects, as well as large phase discontinuities, f.i., associated to steep height variations, affect the reliability of phase unwrapping algorithms (Ghiglia and Pritt 1998).

Multipass SAR Interferometry

Satellites regularly repeat orbits over the time. As a consequence, stacks of multipass acquisitions, characterized by angular and temporal diversity, are available in remote sensing archives for most of the Earth surface. In order to achieve a higher accuracy in the estimation of the deformation, modern advanced DInSAR processing algorithms jointly process all the images in stacks of multitemporal acquisitions: this processing allows in fact to provide a discrimination between the atmospheric and deformation as well as to cancel possible residual topography components.

Among all, interferometric techniques can be distinguished in two main categories which are characterized by complementary assumptions about the ground scattering: the multipass DInSAR stacking techniques and the Persistent Scatterers Interferometry (PSI). The class of the DInSAR stacking methods is a direct extension of the classical two-pass DInSAR technique. It assumes the scattering to be spatially distributed over the resolution cell and is based on the exploitation of both only small (temporal and spatial) baseline interferograms (hard baseline thresholding) and of a spatial multilook in order to limit the effects of decorrelation and reduce the phase noise in the interferograms, as for the Small Baseline Subset technique (Berardino et al. 2002). It is tailored to the monitoring of wide areas and scattering mechanisms that exhibit decorrelation including rural areas with

SAR Tomography for 3D Reconstruction and Monitoring, Fig. 3 Post-seismic deformation velocity map and co/post-seismic time series of a point in the Paganica

area close to L'Aquila obtained by processing a dataset of 33 Cosmo-SkyMed images acquired between April 4 and October 13, 2009 (Reale et al 2011b)

slow temporal correlation losses. This technique relies on the inversion of the linear system relating interferometric (differential) phase values after phase unwrapping to the phase values on each acquisition. The separation of displacement and atmospheric contribution is carried out by exploiting their statistical characterization in terms of spatial and temporal correlation. DInSAR stacking methods analyze interferograms typically generated by pairing acquisitions characterized by small spatial baselines and temporal separation, thus limiting the decorrelation. They play a favorable role in the design of a two-scale processing: besides effectively counteracting decorrelation and phase noise, the spatial multilooking allows also to under-sample the interferograms in the image spatial (azimuth and range) coordinates, thus reducing the amount of data and consequently the computational effort for the analysis of large areas. Therefore, this class of algorithms is particularly suitable for the analysis of large areas at lower resolution

(small scale). Additionally, through the analysis of multiple interferograms, the atmospheric phase contribution can be estimated and compensated from the data. This latter, coupled with the removal of the background deformation signal occurring on a small scale, are used to phase calibrate the full resolution data for processing at large scale, i.e., at the level of single building and infrastructure.

A typical product of the processing through DInSAR stacking techniques is reported in Fig. 3: it represents the deformation mean velocity map, superimposed to a Google Earth image, corresponding to the slope of the deformation time series for each pixel selected by looking at a quality index measuring the temporal consistency of measurements after phase unwrapping. The processing has been carried out through the application of the Enhanced Spatial Differences (ESD) technique which extends the classical SBAS approach by exploiting a model for the phase differences between adjacent pixels to

counteract the effect of atmospheric contribution, thus supporting the phase unwrapping step and increasing the coverage and accuracy of the retrieved deformation measurements (Fornaro et al. 2009b). The result is relevant to the dataset of Cosmo-Skymed acquisitions over the area of L'Aquila, in the central part of Italy, struck by the 2009 earthquake. During the emergency acquisition plan, the Cosmo-Skymed constellation, at that time composed by three of the four satellites nowadays operatively, intensified the acquisition to its highest possible rate (almost 1 acquisition every 5 days on average) to acquire in only 6 months datasets on ascending and descending orbits on different beams including a sufficient number of images for multipass differential interferometric processing. The result presented in Fig. 3 is relevant to the processing of 33 H-image ascending acquisitions (beam 09 corresponding to an incidence angle of about 40°) taken between April 4 and October 13 2009. Colors in the map move from blue, associated to movements toward the radar los (uplift), to red, associated to movements away from the sensor (subsidence). The velocity map (evaluated only on the post-seismic dates from April 12 to October 13) overlaid to a Google Earth image shows an area of subsidence with a rate exceeding the limit of 6 cm/year affecting the city of Paganica, in the eastern part of L'Aquila. In the same image, the plot of the time series of a point in the subsidence area shows the jump associated to the main shock (April 6) and the exponential decay of the subsidence with the aftershocks. Measurements were shown to be in full agreement with traditional leveling (Reale et al. 2011b) and GPS measurements (D'Agostino et al. 2012).

The second class of multipass techniques, the Persistent Scatterer Interferometry, as for SAR tomography, works at the highest spatial resolution to determine the deformation of single dominant scatterers typically associated with man-made structures (dihedral and trihedral of walls edges, poles, gratings, etc.) (Ferretti et al. 2000, 2001). In this case, to achieve also high accuracy in the estimation of the localization of scatterers, no limitations on the spatial baseline are introduced. Similarly to DInSAR stacking

and differently from SAR tomography, PSI uses only the phase information and assumes the presence of a single persistent scatterer per resolution cell retaining correlation over the time (persistent scatterers). The use of the model however presumes the compensation of phase contributions such as the atmospheric phase delay. Such a compensation can be carried out either by analyzing the phase on persistent scatterers (PS) candidates, which are strong scatterers where the phase is less affected by noise or by using the coarse resolution product of previous stacking techniques. In the latter case, a good practice is also to subtract the low-resolution, spatially correlated, deformation so to obtain also a zero deformation steering to carry out high-resolution analysis on residual phase signals; the following model is assumed for the vector $\boldsymbol{\varphi}$ collecting the compensated phase values in the N available acquisitions at full resolution

$$\boldsymbol{\varphi} = \frac{4\pi}{\lambda} \frac{\mathbf{b}}{r} s + \frac{4\pi}{\lambda} \mathbf{d}(s, \mathbf{t}) + \boldsymbol{\varphi}_n \quad (2)$$

where $\mathbf{b}$ is the N -dimensional vector of spatial baselines and $\mathbf{d}(s, \mathbf{t})$ is the vector collecting the displacements measured at the acquisition instants collected in the vector $\mathbf{t}$. Following the compensation for low-resolution components, deformations are divided into the linear, described by the average (mean) velocity v of the pixel corresponding to the slope of the time series wrt to the epochs, and nonlinear $\mathbf{d}_{nl}$ addenda, i.e., $\mathbf{d}(s, \mathbf{t}) = v\mathbf{t} + \mathbf{d}_{nl}$.

PSI assumes nonlinear terms having a small amplitude and carries out, for each pixel, a measure of the correlation of the measured signal with the model in Eq. 2, through the maximization of the scalar product in the following, which returns also an estimation of the (s, v) parameters:

$$C = \max_{(s, v)} \frac{1}{N} \left| \left(e^{j\boldsymbol{\varphi}} \right)^H e^{j\frac{4\pi}{\lambda} \left(\frac{\mathbf{b}}{r} s + v\mathbf{t} \right)} \right| \quad (3)$$

Only pixels for which C is above a fixed threshold are labeled as persistent scatterers and therefore the algorithm provides the temporal series as a product.

In the recent literature, the SqueeSAR approach has been proposed as an extension of the PSI technique to handle the impact of target decorrelation of distributed scatterers (Ferretti et al. 2011). SqueeSAR performs a phase filtering of the interferograms by exploiting the correlation matrix estimated from the data. SqueeSAR extends PSI to partially correlated (i.e., decorrelating) scatterers: the algorithm looks for a persistent scatterer (PS) mechanism equivalent to the real distributed scatterer, i.e., it assumes the response of the equivalent scatterer characterized only by phase variations with constant amplitude. Similarly to DInSAR stacking, SqueeSAR is tailored to the analysis of rural areas, however it does not perform a hard threshold on the baselines but rather it uses in a weighted way all the interferograms.

SAR Tomography System Model

SAR tomography is a step forward, respect to PSI: both are designed to monitor, at the full available spatial resolution, the deformation affecting ground scatterers. The key difference is however the different assumptions of the nature of the scattering which reflects into the interpretation of the received signal. As PSI processes only the phase information interferograms and therefore assumes the presence of a single scattering mechanism, SAR tomography removes this latter hypothesis and considers the complex value of each image pixel measured at the generic n th acquisition as the superposition of multiple elementary backscattering contributions distributed along the elevation s (Reigber and Moreira 2000; Gini et al. 2002; Fornaro et al. 2005). Differential tomography exploits the multitemporal characteristics to allow tomography to also monitoring deformation of scatterers. Particularly, a Fourier expansion of the deformation term $d(s, t)$ is introduced and, assuming the atmospheric phase delay caused by the propagation in atmosphere being compensated through a preliminary multipass DInSAR processing (f.i., SBAS), the measured signal at the generic antenna is therefore modeled as (Lombardini

2005; Fornaro et al. 2009a; Zhu and Bamler 2010a):

$$g_n = \iint_{I_s I_v} \gamma(s, v) e^{j \frac{4\pi b_n s}{\lambda r}} e^{j \frac{4\pi v t_n}{\lambda}} ds dv + w_n \quad (4)$$

which shows that, but for the noise term w_n , a 2D Fourier transform (FT) relationship stands between the data g_n and the backscattering distribution γ in the elevation/velocity (s, v) domain with respect to the Fourier conjugate variables $\xi_n = -2b_n/(\lambda r)$, associated with the elevation s , and $\eta_n = -2t_n/\lambda$, associated with the velocity v . In particular, as a consequence of the deformation term Fourier expansion, $\gamma(s, v)$ plays in v the role of the spectrum of the motion-related signal for elevation s . For linear deformation, the spectral velocity coincides with the deformation rate, i.e., $d(s, t_n) = vt_n$, and then v is usually referred to as deformation mean velocity, whereas for more complex motion, v identifies the (velocity) harmonic involved in the motion.

The tomographic problem consists of the estimation, in each image pixel, of the scene backscattering distribution $\gamma(s, v)$ starting from the N samples g_n and involves, in the most general case, the inversion of Eq. 4, that is, a spectral analysis of the data. This analysis moves the interferometric processing toward an imaging problem approach which extends the classical azimuth compression concepts widely known in the SAR 2D image focusing also for the third (elevation) dimension. Large antenna spans are coherently processed to achieve narrow responses and improve height resolution to the order of meters, allowing separating backscattering from source which are located at different heights. The scattering sources in the pixel can be spatially concentrated (compact scatterers), as for the layover in urban area where scatterers are typically located on the roofs and facades of building and interfere with those at lower heights, f.i., on the ground, or can be distributed along the elevation as for application in forest scenario where separation of ground level from canopy is of interest (Reigber and Moreira 2000; Cloude 2006; Tebaldini 2010).

The 4D model in Eq. 4 represents the most general imaging model which can be

particularized under specific conditions: in case of simultaneous acquisitions implying the absence of temporal diversity, as well as in case of absence of deformation, the signal model reduces to a 1D Fourier transform, and then the backscattering profile $\gamma(s)$ is of interest. This introduces to the 3D imaging framework. On the other hand, whereas uniform motion mostly applies for classical risk situations associated to slow, long-term deformation phenomena, more complex behavior can be also taken into account: the analysis of latest X-Band SAR data points out a higher sensitivity to small changes as those caused by the thermal dilation of materials (Reale et al. 2011a; Zhu and Bamler 2011). Moreover, since revisiting times are reduced with respect to the former generation of SAR sensors, the time requested to collect a sufficient number of images for reliable application of tomographic processing reduces to the order of 1 year, whereas typical C-Band ENVISAT and ERS acquisitions spanned a temporal interval of observation spanning several years. The reduced observation times may imply possible correlation with linear deformation behavior and impair the estimation of the deformation mean velocity (Reale et al. 2013). Even so, the sensitivity to thermal dilation can be exploited by SAR tomography as well. By extending the deformation model to account also for a second contribution linearly related to the average temperature T_n at the acquisition instants, i.e., $d(s, t_n) = vt_n + kT_n$, the order of the tomographic imaging can be extended (5D imaging) to estimate also a coefficient k which measures the expansion along the line-of-sight for each degree of temperature change (Zhu and Bamler 2011; Reale et al. 2013). In application to the monitoring of strategic infrastructures, this strategy allows estimating the stress induced by the temperature changes over the different segments of the structures (Fornaro et al. 2013).

SAR Tomography Imaging Algorithms

Multidimensional SAR imaging algorithms proposed in the literature typically work on

a discretized version of the model in Eq. 4: letting $\boldsymbol{\gamma} = [\gamma(s_0, v_0), \dots, \gamma(s_{M-1}, v_{M-1})]^T$ be the vector that collects the $M = M_s \times M_v$ samples of $\gamma(s, v)$ at the discrete points, hereafter called bins, (s_m, v_m) , with $m = 0, \dots, M-1$, belonging to the $M_s \times M_v$ elevation/velocity discretization grid (T defines the transposition operator), and $\mathbf{g} = [g_0, \dots, g_{N-1}]^T$ and $\mathbf{w} = [w_0, \dots, w_{N-1}]^T$ the vectors collecting, for each pixel, the measured complex data and the noise contribution at each acquisition, respectively, the FT operator in Eq. 4 can be rewritten in the discrete case as

$$\mathbf{g} = \mathbf{A}\boldsymbol{\gamma} + \mathbf{w} \quad (5)$$

where $\mathbf{A} = [\mathbf{a}_0, \dots, \mathbf{a}_{M-1}]^T$ is the $N \times M$ system matrix collecting the steering vectors associated with each discretization bin synthetically defined as $\mathbf{a}_m = \mathbf{a}(s_m, v_m)$, whose generic element is $[\mathbf{a}_m]_n = \exp[-j2\pi(\xi_n s_m + \eta_n v_m)]/\sqrt{N}$.

Several techniques can be used to implement the imaging, that is, the inversion of Eq. 5 that leads to the estimation of the backscattering distribution in the elevation/velocity plane (s, v) . Each is characterized by a different trade-off between simplicity, computational efficiency, sidelobes reductions, and super-resolution capability.

The beamforming (BF) technique represents the classical method to perform the inversion of Eq. 5: it makes use of the conjugate operator $\mathbf{A}^H$, with H being the Hermitian (conjugate transpose) operator, to profile the backscattering along the elevation bins (Fornaro et al. 2009a):

$$\hat{\boldsymbol{\gamma}} = \mathbf{A}^H \mathbf{g}. \quad (6)$$

Once the backscattering in the (s, v) plane has been estimated, scatterers are selected by looking for strong peaks in $\hat{\boldsymbol{\gamma}}$. In this context, a tool for the effective selection of reliable scatterers is required: since in real data the useful information is corrupted by noise, a detection stage is required to control the false alarm rate, defined as the probability to declare the presence of a scatterer, whereas the scatterer is not really present on the ground. With reference to the case of a single

scatterer pixel, a test statistic based on the generalized likelihood ratio test has been proposed in the literature: it provides at the same time the maximum likelihood estimation of the (s, v) pair and declares the presence (hypothesis $\mathcal{H}_1$) or absence (hypothesis $\mathcal{H}_0$) of the scatterer for a given probability of false alarm by exploiting a test statistic which is strictly related to the BF reconstruction and is expressed as (De Maio et al. 2009):

$$\max_{(s,v)} \frac{|g^H a(s,v)|}{\|g\| \|a(s,v)\|} \underset{\mathcal{H}_0}{\overset{\mathcal{H}_1}{\geq}} T \quad (7)$$

where T is the detection threshold, belonging to the $[0, 1]$ interval and set according to the desired level of false alarm. It is worth noting that for single scatterers, the test statistic represents the highest peak of the normalized BF reconstruction and the argument of the maximization is just the

ML estimation of the (s, v) parameters. The GLRT in Eq. 7 allows also demonstrating the effectiveness of an imaging approach, as in SAR tomography, with respect to the classical interferometric processing. The PSI technique, in fact, exploits a similar test but for the use of only the phase information of each element of the vector g (Ferretti et al. 2000, 2001): the exploitation of the whole complex, amplitude plus phase, data as in Eq. 7 provides a significant increase, with respect to PSI, of the detection probability for a fixed false alarm rate.

Typical products achieved by the sequence of low-resolution DInSAR stacking techniques for the derivation of coarse-scale deformation and calibration of data for the subsequent full resolution processing is reported in Figs. 4 and 5. The processing involved a dataset of 29 Cosmo-SkyMed images acquired over the city of Rome, Italy, from April 2011 to October 2012 in H-image mode which provides images with 3 m

SAR Tomography for 3D Reconstruction and Monitoring, Fig. 4 Small-scale deformation mean velocity map estimated by the ESD technique on a dataset of 29 Cosmo-SkyMed images over the city of Rome, Italy.

Colors are set on the estimated velocity and correspond to movements toward the sensor (uplift) in blue and away (subsidence) in red. Optical image courtesy of Google

SAR Tomography for 3D Reconstruction and Monitoring, Fig. 5 3D visualization of the scatterers, represented as *dots*, detected by the GLRT after 4D beamforming reconstruction. *Colors* are set according to

the estimated deformation mean velocity. The area is relevant to the Grotta Perfetta area in Rome, close to the Tevere River. Optical image courtesy of Google

of spatial resolution. According to the SBAS approach, a total number of 80 interferograms has been generated by imposing maximum spatial and temporal baseline spans of 1,000 m and 150 days, respectively. A multilook has also been carried out through the use of a 16×16 pixels moving average filter followed by a subsampling of the same factor. In Fig. 4 it is shown the deformation mean velocity map, superimposed to a Google Earth image, corresponding to the slope of the deformation time series for each pixel selected by looking at a quality index measuring the temporal consistency of measurements after phase unwrapping. As for the L'Aquila dataset, the low-resolution processing has been carried out through the ESD technique. Colors in the map move again from blue (uplift) to red (subsidence). The results highlight the presence of a distributed deformation pattern in the western part of the city which largely affects also the Rome airport. The large number of detected scatterers can be appreciated, although visualization constraints of the Google Earth environment impose a reduction of the total number of points, in this case of a factor 5. The dynamic range also

hides some deformation signals occurring in the central part of the city, which is of interest for the application of full resolution tomographic analysis provided in a following section.

Figure 5 provides a close view, in a Google Earth framework, of the results of the application of 4D imaging and subsequent GLRT detection on the Cosmo-Skymed dataset over Rome introduced before. It allows attesting the capabilities of imaging approaches in the single building monitoring. The area, in the Rome city center, is affected by a severe subsidence induced by the consolidation of the alluvial sediments of the Tevere river. Each dot corresponds to a detected scatterer after geocoding from the original radar geometry to the natural geographic coordinates system: the correct estimation of heights allows effectively positioning scatterers, as they overlap the 3D models provided by Google Earth. Furthermore, the colors correspond to deformation velocity rate estimated for each scatterer: several buildings in the area suffer for large subsidence rates which cause extensive structural damages affecting their stability (Arangio et al. 2013).

The detection problem can be straightforwardly extended to the case of multiple scatterers per resolution cell, which may occur in layover areas. In this framework, a detector which tests the presence of possibly a maximum of two scatterers based on a sequential use of the GLRT discussed above has been also presented (Pauciuolo et al. 2012). With reference to the separation of interfering scatterers within the same image pixel, in application to a real acquisition scenario, the acquisition geometry poses limitation on the imaging capabilities of BF: the baseline distribution defines the unambiguous elevation range that is the maximum extension allowed in elevation direction to avoid aliasing phenomena. Given Δb_n be the spatial separation between the successive antennas, the unambiguous elevation interval will be $\Delta_s = \lambda r / (2\Delta b)$, where Δb is the average value of Δb_n in case of nonuniform baseline distribution. Moreover, the final elevation resolution of BF cannot exceed the Rayleigh resolution given by $\Delta_s = \lambda r / (2B)$ with B being the total baseline span. In the same way, unambiguous velocity interval and velocity resolution can be also defined as $\Delta_v = \lambda / (2\Delta t)$ and $\Delta_v = \lambda / (2T)$, where Δt and T are the average temporal separation and the total temporal span, respectively. The elevation resolution plays a key role in the capability of distinguishing possible multiple scattering contributions within the same pixel: it implies the minimum separation of scatterers as they can be distinguished as separate scatterers. Latest satellite SAR missions as the TerraSAR-X are characterized by a narrow radius of the orbital tube, leading to small baseline excursions that result in final height resolution of some tens of meters. In application to urban areas, such a resolution can be very restrictive for the solution of the interference due to the layover. Finally, in all the practical applications, baselines are far from being uniformly distributed, thus BF gives poor reconstruction performances in terms of sidelobes and leakage in the (s, v) point spread function. Alternative strategies can be adopted to improve both the resolution performances and also the quality of the reconstruction of $\hat{\gamma}$ in the

presence of highly uneven baseline distributions and at the same time achieve some super-resolution capabilities, i.e., the possibility to push the height resolution below the inherent Rayleigh limit.

The use of the singular value decomposition (SVD) of the operator $\mathbf{A}$ in Eq. 5 allows regularizing the inversion by restricting the solution space and benefiting of the inclusion of very limited a priori information on the expected scene elevation extent. The regularization, obtained through the so-called Truncated SVD, allows avoiding noise amplification and inversion instabilities and hence generally provides a better sidelobe reduction and as well as slight super-resolution than plain BF (Fornaro et al. 2009a).

Compressed sensing (CS) is a recent technique used in linear inversion problems for signal recovery that takes benefit of the hypothesis that the signal to be reconstructed have (in some basis) a sparse representation, i.e., a small number of nonzero entries. Under certain assumptions of the measurement matrix, the signal can be reconstructed from a small number of measurements. SAR tomography in urban areas is a favorable application scenario for CS due to the fact that for typical operative frequencies, the scattering occurs only on some scattering centers associated with ground, facades, and roofs of ground structures (Zhu and Bamler 2010b; Budillon et al. 2011).

Summary

Available high-resolution synthetic-aperture radar imaging sensors are capable of providing, in a systematic regular basis, images of single buildings and ground targets with very high spatial details. Persistent Scatterers Interferometry techniques have been already shown to largely benefit of the use of very high-resolution data to monitor buildings. Despite the spatial resolution increase, the steepness of the topography corresponding to vertical structured targets

generates critical distortion effect, the most critical ones are shadow and layover. These are major impairing sources in the analysis of SAR images corresponding to urban areas. SAR tomography represents a powerful technique which allows the implementation of a radar scanner from the space with large 2D antennas to scan the details of building and overcoming problems of layover to generate dense point-cloud measurements of buildings. Multidimensional SAR imaging, based on the concept of SAR tomography, is a tool that represents the most advanced method in the 3D reconstruction and monitoring of buildings. PSI and SAR tomography with very high-resolution sensors provide a unique tool for application of spaceborne microwave radar imaging to urban areas, which is expected in the near future to play a key role in vulnerability and damage assessment of buildings and infrastructures.

Introduction

Access to education is a basic human right. It is enshrined in Convention on the Rights of the

Child (1990), the World Declaration on Education for All (in 1990), and the World Education Forum (WEF 2000). It is one of the Millennium Development Goals for the decade starting in 2005 and continues to be part of the “post-2015” development agenda. Education is strongly associated with poverty reduction, and there are strong global and national drives to implement it. The Global Partnership for Education has 29 national partners, supporting the implementation of universal, free, quality basic education in 57 partner developing countries. In GPE’s 2012–2015 Strategic Plan, the first of its four strategic goals is “All children have access to a safe, adequately equipped space to receive an education with a skilled teacher.” However, none of its monitoring indicators mention safety. Since 2004, the GPE has contributed to build, rehabilitate, and equip close to 53,000 classrooms (GPE 2014). However, up until at least 2013, there was no systematic due diligence with respect to disaster-resilient construction. In the rush to fulfill the right to education, are children being put at risk?

This entry assesses seismic threats to schools and reviews incidents of children and teachers killed by structural failure of school buildings as well as structural damage to schools and near misses. It reviews progress, good practices, and lessons learned based on these threats. The entry goes on to overview school vulnerability, global experiences in seismic-resistant school construction, and retrofit. A summary of progress in school seismic safety along with a recommended systematic all-hazards approach to comprehensive school safety set the stage to make the case for continued advocacy for school seismic safety.

The Threat

According to estimates made by the Center for International Earth Science Information Network at Columbia University in 2006, there are more than 100 million school-aged children exposed to significant seismic risk throughout the world (New York Times 2008). In 2004, 10 of the 16 contributors to this article initiated recording

of case studies on progress and struggles for school seismic safety which are updated in the entry “► [School Seismic Safety: Case Studies](#).” They set out the magnitude of concern and main arguments for advocacy in an unpublished article. At the time, the authors posited the gruesome estimate of “4,800 school children killed by earthquake-related school collapse or severe damage over the next decade. . . It might be reasonable and prudent to plan to avoid a loss of student life in earthquakes of somewhere between 2,000 and 5,000 in a 10 year period.” At the time it was written, this estimate seemed to the authors to be somewhat alarmist.

The following year, shortly after the unprecedented destruction caused by the Indian Ocean earthquake and tsunami, 168 countries agreed to the 2005–2015 Hyogo Framework for action. Over the course of this 10 year period, this dire predication has been exceeded fourfold as the result of only two major earthquakes during school hours: the 8 October 2005 Kashmir earthquake which killed more than 18,000 students, in addition to staff, in schools, and the 12 May 2008 Sichuan earthquake which killed more than 5,300 students, in addition to staff, in their schools (UNISDR 2008).

In the powerful earthquake and massive tsunami on 11 March 2011 in northern Japan, schools themselves were by and large structurally sound and resisted earthquake damage, but tsunami-retaining walls were breached as the tsunami was larger than expected and land subsidence had not been factored in. Disaster drills and practice of “tendenko” (automatic tsunami evacuation), by many school children, saved many lives. Some schools provided vertical evacuation, and many survived at evacuation and shelter centers. But instances of confusion occurred and many school pupils and teachers also died. Today, the students now displaced by the resulting nuclear disaster recognize this neglected threat as the most catastrophic of all. The international community is virtually silent on this threat.

In common with other infrastructure, school buildings are subject to damage and collapse in earthquakes. Many of these have resulted in children killed while being educated (Table 1).

Pictorial evidence of historic earthquake damage to schools is available in the NISEE, Earthquake Engineering Online Archive.

There have also been many cases when an earthquake destroyed school buildings when they were not in session, and thus deaths and injuries were narrowly avoided (Table 2). However the severe impact on continuity of education and the potential magnitude of loss of life in these events further highlight the

importance of ensuring the seismic safety of schools.

Making the Case for School Seismic Safety

Many public buildings and different sorts of critical infrastructure are threatened by earthquakes. The case can be made for giving priority to

School Seismic Safety and Risk Mitigation, Table 1 Children killed by structural failure of school buildings

Date/local time (Source)	Location/magnitude ^a	Consequences/schools	Consequences/children
12 Jan 2010 16:53 (CNN 2014)	Port-au-Prince, Haiti M 7.0	MoE estimates 4,992 schools affected (23 % of the nation's schools)	Deaths and injuries unknown. Many children with disabling injuries. Some schools were holding their third shifts. Est. 1.3 m children and youth affected
12 May 2008 14:28 (COGGS 2008)	Wenchuan, China M.7.9	175 schools (7,000 classrooms) in Sichuan and Shaanxi provinces were destroyed	>5,300 school children died in dozens of schools In the Beichuan Middle school, 1,300 of 2,999 students and teachers died
6 Mar 2007 11:00 (COGGS 2008)	Western Sumatra M 6.4	The wall of a primary school collapsed. Fire followed. Up to 329 schools affected by several earthquakes (2005–2010)	4 primary school children died

13 April 1949 11:58 (COGGS 2008)	Olympia, Washington, USA M 7.1	10 schools destroyed, 30 damage. Spring break	2 children in school were killed
31 October 1935 (COGGS 2008)	Helena, Montana, USA M 6.2	Newly built secondary school wing collapsed	2 students killed. Classes not in session, could have been much worse
10 March 1933 Long Beach (COGGS 2008)	Long Beach, California, USA M 6.4	70 schools destroyed. 120 with major damage. Classes held in tents for 2 years. First legislation for safe school construction	2 children died in gymnasium collapse. Spring break, classes not in session, could have been much worse

^aMagnitudes from USGS or Wikipedia

schools from three perspectives: Duty bearers have moral and legal obligations to fulfill children's rights to both safety and survival and educational continuity. In more affluent countries, the cost benefits of investments in public safety, the importance of safeguarding development investments, and preventing educational disruption are undisputed. And, the uses of school buildings as multipurpose community centers and disaster shelters, even when children are not harmed, have cascading social and economic

consequences beyond the replacement cost of school buildings themselves. In most cases public discussion and debate on these issues tend to mix these ethical and pragmatic arguments.

Human Rights Argument

The human rights argument suggests that no society should tolerate a choice between the safety of children's lives and their education. The right to

School Seismic Safety and Risk Mitigation, Table 2 School structural damage from earthquakes

Date (Source)	Location/magnitude ^a	Structural and educational impacts
2 July 2013 14:37 (Pandey 2013)	Aceh, Indonesia M 6.2	966 schools affected
4 April 2010 15:40 (Rodgers 2012)	California, USA, and Baja, Mexico M 7.2	Significant structural damage to several schools in Mexico. Significant nonstructural damage to several schools in the USA. Cost of repair almost 20 % of annual budget for one school district. School was on spring break. Nonstructural damage would have caused injuries and blocked egress. In California hazardous asbestos from collapsed walkways and mercury from light fixtures closed schools for extended periods
30 September 2009 17:16 (Rodgers 2012)	Padang, West Sumatra, Indonesia M 7.6	2,164 severely damaged, 1,447 moderately damaged, 1,137 lightly damaged School was recently dismissed for the day. Temporary school buildings of timber frame and corrugated steel
2 September 2009 14:55 (Pandey 2013)	West Java, Indonesia M 7.0	716 schools affected
21 September 2009 14:53 (Rodgers 2012)	Mongar, Bhutan M 6.1	91 schools affected: 6 destroyed, 17 required major repair, 44 required partial repair, 24 required minor repair (cost 12.9 m USD) plus damage to boarding schools, water, and sanitation School was dismissed early for holiday. Temporary learning facilities inadequate for weather
6 April 2009 03:32 (Rodgers 2012)	L'Aquila, Italy M 6.3	78 schools had extended closures and 12 partial closures
12 September 2007 18:10 (Pandey 2013)	Bengkulu, Indonesia M 8.5	240 schools affected (2005–2010)
15 August 2007 23:40 (Rodgers 2012)	Pisco, Peru M 8.0	116 schools were severely damaged. 478 classrooms were needed to restore school activities
27 May 2006 05:53 (Rodgers 2012)	Yogyakarta, Indonesia M 6.3	Yogyakarta: 2155 educational facilities damaged or destroyed; Central Java: 752 damaged or destroyed. Damage and losses estimated at 1.7 trillion Indonesian Rupiah
26 December 2004 early am (UNISDR 2008)	Indonesia, Sri Lanka, Maldives, Thailand M 9.1–9.3	School earthquake and tsunami damage combined: Indonesia – 750 destroyed 2,135 damaged. Sri Lanka – 51 destroyed, 100 damaged. Maldives – 44 destroyed or damaged. Thailand – 30 destroyed
26 December 2003 5:26 (COGGS 2008)	Bam, Iran M 6.6	67 of 131 schools collapsed. The remaining 64 were heavily damaged and unusable 33,000 students were affected
22 September 2003 12:45 (UNISDR 2008)	Puerto Plata, Dominican Republic M 6.4	50 public schools damaged, 140 classrooms impacted 18,000 students were without classrooms
21 May 2003 19:48 (COGGS 2008; OECD 2004)	Boumerdes, Algeria M 6.8	130 schools damaged beyond repair. 753 schools extensively damaged or destroyed The earthquake occurred out of normal school hours, so children were not at school. Cost of school rehabilitation \$79 million+
24 February 2003 (COGGS 2008)	Xinjiang, China	Dozens of schools collapsed The earthquake struck 27 minutes before thousands of children would have been in classrooms
25 April 2002 22:41 (Rodgers 2012)	Tbilisi, Georgia M 4.5	Approximately \$8 million US in school damage. No collapses; 1 school with very heavy damage; 35 with substantial damage; 68 with moderate damage; 98 with negligible or slight damage

(continued)

School Seismic Safety and Risk Mitigation, Table 2 (continued)

Date (Source)	Location/magnitude ^a	Structural and educational impacts
21 September 1999 1:47 (COGGS 2008)	Chi-Chi, Taiwan M 7.7	51 schools collapsed. 786 schools nationwide were damaged. 22 % of schools and 71 % of post-secondary institutes damaged The earthquake happened in the middle of the night, so no one was in the building. Cost of repair and reconstruction \$1.3 billion
June 23 2001 15:33 (COGGS 2008)	Arequipa, Peru	98 school buildings seriously damaged School not in session on Saturday
17 August 1999 3:02 (COGGS 2008)	Kocaeli, Turkey M 7.6	43 schools were damaged beyond repair. 381 minor to moderate damage In Istanbul 60 km away 35 schools were unsafe and demolished School was not in session but was suspended for 4 months. In Istanbul 131 schools were closed temporarily, for inspection
25 January 1999 13:19 (OECD 2004)	Pereira and Armenia, Colombia M 6.2	74 % of schools in Pereira and Armenia were damaged School was not in session
20 August 1998 (UNISDR 2008)	Udayapur, Eastern Nepal M 6.6	1,200 schools heavily damaged or destroyed. 6,000 affected
17 July 1998 00:19	Papua, New Guinea M 7.0	Schools destroyed
9 July 1998 5:19 (COGSS 2008)	Faial, Azores, Portugal M 6.2	Schools damaged School was not in session
20 May 1998	Afghanistan/Tajikistan M 6.6	Unknown
12 November 1996 15:33 (COGSS 2008)	Nazca, Peru	93 school buildings seriously damaged
1996 (OECD 2004)	Temouchent, Algeria M 5.6	6 schools destroyed, 17 moderate damage, 36 light damage
17 January 1995 5:46 (COGSS 2008)	Hanshin-Awaji, Japan M 6.9	54 buildings school damaged beyond repair. Extensive earthquake and fire damage to 4,500 educational buildings. ¥94 billion. School was not in session
1994 (OECD 2004)	Beni Chourgrane, Aleeria M 5.6	4 schools destroyed, 16 moderate damage, 30 light damage
17 January 1994 04:31 (FEMA 2011)	Northridge, California, USA M 6.7	24 of 127 affected schools suffered significant structural damage. Suspended lighting and ceiling systems were damaged in 1,500 buildings 2, 204 schools were used as shelters. Had this occurred during the school day, significant injuries and lack of safe egress for thousands would have resulted. The Los Angeles Unified School District, amongst others, embarked on projects for nonstructural mitigation, now the responsibility of school maintenance personnel
25 March 1993 (COGSS 2008)	Scott Mills, Oregon, USA	Part of masonry school building collapsed Spring break, school was not in session
17 October 1989 17:04 (EERI 1990)	Loma Prieta, California, USA M 6.9	7 schools in three districts and one headquarters sustained severe damage. 1,544 were schools surveyed. Total value of damage \$81 million USD
10 October 1989 (OECD 2004)	El Asnam, Algeria M 7.3	70–85 schools suffered extensive damage or collapsed The earthquake occurred out of normal school hours, so children were not at school
20 August 1988 4:39 (COGSS 2008)	Bihar, India, and Udaypur Nepal M 6.6	950 school buildings were damaged in Bihar 6,000 schools destroyed in Nepal School was not in session

(continued)

School Seismic Safety and Risk Mitigation, Table 2 (continued)

Date (Source)	Location/magnitude ^a	Structural and educational impacts
8 November 1988 (UNISDR 2008)	Yunan, China	1,300 schools destroyed in earthquake
19 September 1985 :17 (COGSS 2008)	Mexico City, Mexico M 8.0	137 school buildings collapsed, 1,687 school buildings were damaged Schools were not yet open
2 May 1983 23:42 (COGSS 2008)	Coalinga, California, USA	Extensive nonstructural damage noted
10 October 1980 13:25 (OECD 2004)	El Asnam, Algeria M 7.3	70 schools totally destroyed, 25 moderately damaged School was not in session
9 February 1971 06:01 (State of California 2009)	Sylmar, California, USA M 6.6	Only 4 of 1,544 buildings surveyed suffered severe damage. Nearly all damage was nonstructural School was not in session
31 May 1970 4:23 (COGSS 2008)	Chimbote, Peru M 7.9	6,730 classrooms collapsed and hundreds seriously damaged
27 March 1964 (COGSS 2008)	Alaska, USA	Primary school destroyed by an earthquake-induced landslide. Half of Anchorage's schools were significantly damaged The earthquake struck on a holiday, Good Friday, so schools were closed
1963 (COGSS 2008)	Skopje, Macedonia	44 schools (57 % of urban stock) were damaged 50,000 students affected. Sunday, school not in session
21 July 1952 4:52 (COGSS 2008)	Kern County, California, USA M 7.3	20 schools damaged or destroyed (most built before 1933). Significant nonstructural damage also noted
4 March 1952 (USGS 2003)	Sapporo, Japan	400 schools collapsed in Sapporo
10 March 1933 (COGSS 2008)	Long Beach, California, USA	70 schools collapsed The earthquake hit early in the evening after children had left for the day which saved their lives. Five students were killed in a gymnasium
3 February 1931 (Dowrick and Rhoades 2004)	North Island, New Zealand	Several schools were severely damaged The earthquake happened at mid-morning during school playtime when the children were outdoors enjoying the summer weather. Some students were killed, but the death toll could have been several hundreds
17 June 1929 10:17	Murchison, New Zealand	College tower and dormitory roofs collapsed School was not in session
18 April 1906 05:12	San Francisco, California USA	28 schools burned in fire. 41 schools damaged or destroyed Classes were not in session

^aMagnitudes from USGS

Bibliographic references on many structural impacts on schools are available on the internet (Rodgers 2012)

life and the right to education are both recognized human rights, and both should be met. This argument takes on additional salience in view of the current international effort to increase school enrollment and attendance by girls, disabled children, and children of the very poor and marginalized groups in society.

Around the world, at least 100 million children of school age do not attend school representing about 14 % of the world's children (UNESCO 2004). Providing facilities to educate them requires construction of schools and rapid expansion of building programs. The Education for All campaign originally

hoped to enroll 24 million of these children in a decade. Millennium Development Goals (MDGs) specifically aim to “[e]nsure that, by 2015, children everywhere, boys and girls alike, will be able to complete a full course of primary schooling.”

In 2004 it was estimated that more than 7,500 new schools were needed within the next 3 years solely in Afghanistan, a country with a significant seismic hazard. It would be ironic and tragic if in the course of achieving one MDG, another is undermined.

Another MDG target is to reduce the under-five mortality rate by two thirds, between 1990 and 2015. On the one hand, the international community is seeking to save the lives of under-fives, only to put them at risk a few years later when they go to school.

Educational authorities charged with the construction and maintenance of schools are also the ones tasked with many other functions: They develop curricula, hire teachers, and choose educational resources such as textbooks and computers. School safety issues have to find a place in the capital, maintenance, and operation budgets of school buildings and school operation.

Retrofitting schools for seismic safety can be perceived to compete for funds with the rest of the educational process. The question facing decision makers can actually appear to be: “What is more important: an up-to-date textbook and good laboratory facilities now or a building that can withstand an extreme event which might or might not occur with the next few decades?”

Under most circumstances, young people do not lobby for their own rights to health and safety. Children cannot refuse to go to school because a building is unsafe. By law, they must attend school, though teachers, parents, and others may advocate on their behalf. Faculty and support staff in schools should also be concerned for their occupational safety and theoretically be natural advocates of safe school facilities. Yet there are no examples mentioned to date of teachers unions becoming involved in the issue of school disaster vulnerability.

Cost-Effectiveness Arguments

There are two forms that cost-effectiveness arguments may take. One asserts that the authority responsible for education incurs greater cost in the long run to repair and replace schools damaged by earthquakes than the cost of enforcing building codes and making sure that every new school is a safe school (or even of retrofitting older or poorly built schools). In some cases, replacement of unsafe schools is more cost-effective than repair (e.g., see entry “► [School Seismic Safety: Case Studies](#),” for examples from Algeria, Colombia, and Turkey). Notable studies of the benefits and costs of retrofitting schools in the USA, Italy, Mexico, and Peru have been published in the decade between 2004 and 2014.

A more ambitious and difficult case to make concerns the relative cost-effectiveness of investments in school seismic safety when compared to investing that money in other kinds of public health, safety, and welfare. In cases where child and infant mortality is high, longevity is shorter, basic vaccinations are not universal, or safe domestic water and sanitation facilities are inadequate, then the relative ranking of school safety as a cost-effective public health intervention may be low. Competition for public health funds could occur in trying to decide between clean water and vaccinations for everyone versus school seismic safety. In more affluent countries, the cost-effectiveness of saving lives in a future disaster usually has a high place among prioritized goals.

Of course, the physical safety of children, both in schools and out in the world at large, goes well beyond school seismic safety. HIV/AIDS, malnutrition, sexual violence, malaria, labor practices, and forced military service are day-to-day threats to the physical safety of many of the world’s children. The small potential for an earthquake over the next century might appear to pale beside other concerns which daily kill many more children.

However, in places where school seismic safety is a prominent issue – such as Tehran, Vancouver, Kathmandu, Bogotá, and Wellington – a significant earthquake has a high

probability of happening during the lifetime of schools currently standing and, therefore, for the gradually changing cohort of children during the life of the building. If earthquakes happen with equal probability around the clock, then approximately a 6–23 % chance exists of schoolchildren being in the school during a damaging earthquake. Cost-benefit studies of seismic construction estimate that it would add about 5 % to the cost of building a school in the USA, and in other countries the highest estimates are about 15 %, making the expectation that “every new school be a safe school” a realistic expectation.

When a population at risk is predominantly children, depending on the country, each death represents 40–70 years of lost life and productivity, and each injury represents 40–70 years of potentially expensive medical care, such as for brain or spinal injuries. Fix schools and several generations of children are protected. Health economics and medical ethics agree that the greatest social benefit comes from investment in the health and capacities of children. Aside from saving lives, the cost of education interrupted, and the serious potential for drop out adds another cost factor that seismic safety could help avoid.

Argument from the School’s Multiple Functions

The symbolic, cultural, economic, and political significance of schools as a community hub gives them an importance beyond merely being the site for educating children. Schools often play roles as central places for meetings and group activities, including literacy classes, religious services, political activities, and marriage ceremonies, particularly in rural areas where the school might be the only location big enough to hold such an event. Schools may also provide essential nutrition programs and serve as makeshift hospitals or vaccination centers even in normal times.

Where schools are the safest buildings in a community, they often serve as temporary shelter from storms and floods. They may be staging areas for first aid or rescue operation or other disaster response functions and even provide

temporary housing, while still fulfilling their role as an education facility.

Thus schools have a value in the social fabric of a community, providing adult education, promoting public health, building and maintaining sustainable livelihoods, and protecting people. The monetary value of those social gains defies estimation but clearly adds value and further justifies investment in safe school construction and maintenance.

We know from many disasters the important role that schools play in anchoring and speeding community recovery. Rapid school re-opening has tangible benefits in terms of children who are safe, supervised, and progressing towards their educational goals. Intangible benefits of schools functioning normally following a disaster include the psychosocial support in the face of loss and change. The importance of operational continuity of schools is linked to community recovery.

To take another example, retrofitting can spread a message far beyond the school. When children see their school being seismically retrofitted, they may have and may be designed to have ripple effects on safer residential construction. However, this is by no means automatic, and just how to maximize school construction or retrofit experience into a wider learning opportunity is a promising line of pursuit. Schools certainly serve as community hubs for propagating the seismic safety messages. School seismic safety can not only protect a community’s children but also educate communities to protect themselves.

Progress, Good Practices, and Lessons Learned

Assessing School Safety from Disasters, A Global Baseline Report (UNISDR 2012) found several consistent threats to safe school facilities:

- **Failure to assure every new school is a safe school:** Neither donors, governments, nor NGO associations have unequivocally committed to providing evidence or assurances or submitted to monitoring to assure that every new school is a safe school. Many small-scale

donors are particularly unaccountable and are not reached by the same accountability mechanisms and efforts of UN agencies and major international non-governmental agencies.

- **Multi-hazard awareness is often lacking:** In the construction of school facilities, there are many examples of fulfilling resilience to one hazard, while failing to mitigate against others – sometimes resulting in schools being dangerous in spite of good intentions or lying unused.
- **Impact of construction on education and family life not well understood:** School remodeling, retrofit, and replacement all have an impact on existing school programs and families. Planning these projects to minimize adverse impacts continues to be a concern.
- **Opportunity for construction and retrofit as an educational experience is untapped:** School construction and retrofit provide ideal opportunities for students and communities to learn the many principles of disaster-resilient construction to be applied throughout their communities. This opportunity is typically wasted as school sites are hidden from view and the experience is not used as a learning opportunity.
- **Lifeline infrastructure failures threaten school attendance:** Vulnerabilities in roads, bridges, and transportation systems must be prioritized when school attendance is threatened.
- **Failure to prioritize school re-opening jeopardizes community recovery:** Schools play a critical role in disaster recovery and community resilience where adults cannot return to work (UNISDR 2012).

The same study found consensus around the following core commitments required for safe school facilities: (1) Every new school must be a safe school. (2) Legacy schools should be prioritized for replacement and retrofit. (3) Lifeline infrastructure and nonstructural safety should be assessed locally and measures taken to mitigate [dangers]. (4) School furnishings and equipment should be designed and installed to minimize

potential harm they might cause to school occupants.

The expert review process that was part of the *Guidelines for Safer School Construction* (INEE 2010) yielded identification of a rich set of enabling factors associated with successful and sustained programs for school structural safety that all school safety advocates need to consider awareness, community ownership, partnership and dialogue, quality assurance, appropriate technology, integrated education, cultivating innovation, encouraging leadership, and continuous assessment and evaluation.

Overview of School Building Vulnerability

Rodgers (2012) reviewed earthquake damage assessment reports through 2009, for 32 earthquakes globally and aggregated findings from 31 school building vulnerability assessments. Table 3 shows the most commonly cited sources of vulnerability from both sources.

The general lack of agreement between vulnerability assessment and damage data likely reflects fragmentary and typically inadequate efforts to collect school damage data following past earthquakes, as well as a tendency for vulnerability assessments to identify common characteristics (such as plan irregularities) that rarely lead to the severe damage noted in post-earthquake damage surveys and reconnaissance reports. More complete earthquake damage data would provide the best indicator of the vulnerability-creating characteristics more likely to cause severe damage, because many vulnerability assessments do not differentiate the severity of damage expected from observed deficiencies.

The sources of and characteristics of structural vulnerability can be summarized in terms of: configuration (large windows with partial height walls below create captive columns or narrow piers, large windows on one side, weak or soft stories, large rooms, buildings one bay wide often with irregular plans), building type (vulnerable forms of vernacular and engineered construction,

School Seismic Safety and Risk Mitigation, Table 3 Characteristics found in damage and vulnerability assessments

Characteristics	Cited in 25 % or more		Cited in 15–24 %	
	Damage assessments	Vulnerability assessments	Damage assessments	Vulnerability assessments
Captive columns due to partial height masonry infill walls under windows	✓	✓		
Non-ductile reinforced concrete frame construction	✓	✓		
Generally poor construction quality	✓			✓
Poor-quality engineered materials	✓			
Soft or weak story		✓		
General plan irregularity		✓		
Exterior falling hazards		✓		
Maintenance deferred or lacking		✓		
Inadequate doors, windows, halls/corridors, or stairs		✓		
Vulnerable masonry construction		✓	✓	
Lack of seismic design understanding by engineers			✓	
Interior architectural and contents hazards			✓	✓
Windows reducing solid wall area in masonry construction				✓
Torsion				✓
General vertical irregularities				✓

Rodgers (2012), pp. 4–5

safer traditional construction forms and practices abandoned, standard building plans with seismic deficiencies, heavy roofs), location (sites susceptible to ground failure, sites that amplify ground motions), construction practices (poor quality, unskilled or low-skilled local labor, reducing quality to save money or time), materials (poor-quality engineered materials, weak local materials), lack of construction inspection, lack of maintenance, subsequent modifications, falling hazards, and inadequate exit pathways (Rodgers 2012).

Underlying drivers create an environment conducive to the vulnerability-creating characteristics cited above. Published literature identifies the following: unregulated community-based construction, scarcity of resources, inadequate building codes or zoning, lack of code enforcement, corruption of enforcement mechanisms, unskilled or unaware building professionals, lack of accountability, lack of awareness, failure to prioritize school safety, and urgent need for large numbers of new schools (Rodgers 2012).

Overview of Global Experiences in Seismic-Resistant School Construction

Some of the major policy and programmatic endeavors to assure seismic resilient construction of schools, worldwide, as of 2013, have involved important steps such as providing risk maps for safe school site selection, construction guidelines, standards, and oversight and commitments to safe school construction in the context of both post-disaster reconstruction and new school construction to meet Millennium Development Goals.

The **provision of risk maps** for safe school site selection requires both national and subnational coordination and often several different agencies reporting on the full spectrum of geophysical and hydrometeorological risks and taking into account nuclear, biological, and chemical hazards. In Peru, a pool of trained consultants based in universities around the country are now available to advise Regional Education Offices on safe school site selection. They draw

from existing risk maps for 115 towns (UNISDR 2008).

In the area of **construction guidance and standards**, California's Field Act in 1933 stands as the starting point of the movement. The Act required 15 % higher performance standards for new school construction and introduced stringent supervision. Legacy school construction was raised as a policy issue as early as 1938 (Garrison Act) but was not enforced until 1968. The oversight system involves structural plans prepared by engineers and approved by the Division of the State Architect. There is recurring on-site inspection and a final verification process.

The more common approach is the development of technical guidance for planning, design, construction, and local ongoing maintenance. There are numerous variations on this theme. For example, in the Philippines, in 2007, the Department of Education adopted the Principal-Led School Building Program approach where principals or school heads take charge of the implementation of management of the repair and/or construction. Assessment, design, and inspection functions are provided by Department of Education engineers who assist the principal during the procurement process. The Parent, Teacher, and Community Association and other community stakeholders are responsible for auditing procurements (INEE 2010). Interestingly, in Panama, it was the development and implementation of the maintenance guidance tool that paved the way for new school construction standards (UNISDR 2012).

There have been several examples of post-disaster commitment to "building back better," emerging from a general consensus following the 2005 Indian Ocean earthquake and tsunami, on the need use humanitarian assistance and reconstruction financing more responsibly. However, in the area of school seismic safety, these good intentions have only translated vaguely to measurable improvements in safe school construction. In Pakistan, 4 years after a devastating earthquake there, the National Education Policy 2009 section 5.5 addressed Education in Emergencies with several policy actions including requirements for school construction according

to international standards (UNISDR 2012). Following the devastating 2010 earthquake in Haiti, many donors stated that the schools that they are supporting seismic, hurricane, and flood-resilient school reconstruction, though there is no program that monitors progress in this regard.

In Indonesia in 2009, the Center for Disaster Mitigation, Institute of Technology Bandung (CDM – ITB), and Save the Children International published a handbook of typical school design and a manual on retrofitting of existing vulnerable school buildings for the Aceh and West Sumatra Earthquake Response programs. The guidelines take into account lessons learned in safe school construction, weaknesses in oversight of local government construction, and the need to incorporate design of dual-purpose multi-hazard shelters. In 2014 they were considered ready for an update.

In the Philippines, following devastating typhoons in 2006, 99 disaster-resilient schools and 26 day-care centers were constructed with the support of the Department of Education engineers, school principals, and community members. The new buildings, with water and sanitation facilities, can also serve as evacuation centers with flexibility to accommodate large numbers of people for emergency shelter (Global Education Cluster 2011).

Following the 1999 Kocaeli earthquake, 820 of 1,651 schools that were 60 km away in Istanbul, were found to have sustained some damage. Thirty-five schools were replaced, 59 schools were strengthened, and 59 were repaired (COGSS 2008).

Clear warrants and commitments from donors IGOs or INGOs when it comes to safe school construction are still clearly much needed.

There have also been too few and/or too quiet **commitments to safe school construction** in the context of the Millennium Development Goals, in spite of the fact that the Global Partnership for Education states as its first strategic goal the provision of a quality basic education in a *safe* environment. The most important and notable has been in Uttar Pradesh, India, where 23.5 million children attend school in this moderate to severe seismic risk zone; 21,000 new school buildings

(30/day) were to be built in a 2-year period. In 2006–2007 the Elementary Education Department proposed to integrate earthquake-resilient design into all new school buildings. One primary school, two upper primary, and three additional classroom designs were prepared with detailed construction manuals. Disaster-resilient measures added 8 % to the construction costs. To cope with massive scale of the project, a cascading approach prepared 4 master trainers for each of 70 districts. These individuals trained 1,100 Junior Engineers and Education Officers. Ten thousand masons were also trained. In Uttar Pradesh every new school is now a safe school (UNISDR 2008).

Overview of Global Experiences in School Seismic Retrofit

In Sichuan, China, Prior to the 2008 Sichuan earthquake, school principal Ye Zhiping pestered local authorities until they consented to retrofit the buildings of Sangzao Middle School to improve their safety. He also initiated regular evacuation drills. The result of his efforts was that during the devastating earthquake, this school provided life safety for all of its students and staff.

The United Nations Center for Regional Development in Kobe began promoting school earthquake safety initiatives in 1999, in the process of resilience-building following the Hanshin-Awaji earthquake. A multi-country school seismic retrofit initiative (2005–2008) sought to make schools safer through self-help, cooperation, and education. The project engaged local communities, governments, and resource institutions in demonstration vulnerability assessments and school retrofit projects in four to six schools each, in Fiji, India, Indonesia, and Uzbekistan. In 2006, the state of Uttar Pradesh, in India, undertook large-scale disaster-resilient construction of new schools (Bhatia 2008). GeoHazards International also conducted small-scale screening and retrofit demonstration projects in vulnerable schools in Delhi, India (Rodgers 2012), and helped Bhutan's Ministry

of Education develop the process and tools for a nationwide school vulnerability assessment program, which is currently underway.

More than a dozen countries have developed approaches, conducted significant vulnerability assessments, and/or made commitments made to school retrofit since 2000. Several of these were inspired by unacceptable levels of damage experienced in recent large earthquakes. Many are instructive or inspiring, in terms of their scope, methods, and limitations. Looking at these regionally allows an overview of both limited scope and adequacy.

Middle East and North Africa: In Algeria, vulnerability assessment was done on 526 buildings in 190 schools across 9 municipalities in Algiers, using simple survey forms (Rodgers 2012). In Syria, UNDP is supporting earthquake school safety program incorporated into 5-year plan and institutions for disaster risk reduction are being consolidated (UNISDR 2012). The Arab League is currently considering a regional approach to disaster risk reduction, which will hopefully include a comprehensive approach to school safety.

North America: In British Columbia, Canada, Vancouver school buildings were surveyed in 1990 (Rodgers 2012). Responding to advocacy efforts of the local "Families for School Seismic Safety," in 2004, the provincial government committed \$1.5 billion Canadian to ensure that BC Schools meet acceptable seismic life safety standards by 2019.

In the USA, there has been detailed assessment of 26 school buildings in Kodiak, Alaska, with recommendation for retrofit of four. In California, a desk assessment of 9,659 pre-1978 school buildings found 7,537 potentially vulnerable buildings. Twenty thousand uncertified projects have been mapped (California Watch 2011). The state of Oregon conducted collapse risk assessment of 2,185 K-12 school buildings using FEMA 154 rapid visual screening (RVS) and produced structural engineering reports for more than 300 buildings. South Carolina has completed a prioritization exercise on all public schools; six have been retrofitted. In Tennessee 49 buildings in 202 schools have been screened using ATC-21

plus local methods, and in Utah, RVS was used on a sample of 128 of 1,085 schools in the state (Rodgers 2012).

Latin America and the Caribbean: The Organization of American States began a commitment to school safety in 1992. A coordinated regional action plan was developed to benefit Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, and Panama. Development assistance donors and local organizations contributed to strategies and capacity to carry out retrofitting of educational facilities. School infrastructure experts from each country received training.

In Bogotá, Colombia, in 1997, seismic microzonation studies paved the way for seismic-resistant building codes in 1998. In 2000 the Directorate of Prevention and Attention of Emergencies in Bogotá found 434 of 710 schools vulnerable to earthquake damage, 3 in flood areas, and 20 in landslide-prone areas. Two hundred and one were prioritized for retrofit or replacement. Between 2004 and 2008, an investment of \$460 m USD in school replacement, retrofit, and risk management promotion provided structural reinforcement of 172 schools, “nonstructural” risk reduction in 326 schools, and the construction of 50 new mega-schools, compliant with earthquake-resistance requirements. Three hundred thousand children are safer as a result (see entry “► [School Seismic Safety: Case Studies](#)” for case study of Colombia). In Ecuador, initial screening of 340 high-occupancy school buildings, and modified RVS of 60 most vulnerable, detailed analysis for 20, and retrofit designs for 15 have taken place (Rodgers 2012). In Lima, Peru, 28 schools in Barranco and 80 schools in Chorrillos were evaluated using ATC 21 RVS and EMS_98 estimation of damage potential (Rodgers 2012). A retrofit solution was developed to mitigate potentially devastating structural defect of “short columns.” And in Venezuela, 50-year-old schools were identified as needing retrofitting in moderate and above seismic zones, whereas 20–30 year-old “box” schools only require retrofit in higher-risk zones. Practical retrofitting techniques were developed. As of 2007, 28,000 schools were being surveyed in a national program. Twelve

schools were selected for pilot retrofits (Rodgers 2012).

Europe and Central Asia: In Europe, discussion has been robust in Italy and Portugal, innovations have been led by UNICEF and partners in Central Asia, and World Bank financing has supported Turkey to make significant progress in seismic safety (see entry “► [School Seismic Safety: Case Studies](#)” for case study on Turkey).

In Yerevan, Armenia, full assessments have been conducted by teams of dozens of people, mobilized from as many as seven different government agencies, over several days. Every year 40 of Yerevan’s 200 schools are slated for special maintenance, upgrading, and retrofitting. It has been noted that a 2-person expert team spending 2 h per conducting a rapid assessment would require 6 FTE years to assess Armenia’s 1,500 schools. In Kyrgyzstan, a national school safety assessment of over 3,000 learning facilities with support from USAID found that more than 80 % were vulnerable to earthquake damage. Public access to this information is made possible through an online portal (UNICEF 2011).

In Uzbekistan 1,000 school buildings were assessed, revealing that 51 % require demolition and replacement, 26 % require capital repair and reinforcement, and 27 % are life safe and require no intervention (Khakimov et al. 2007). Eleven design institutes participated in building code revision for school building construction. Typical designs were created for new schools of different sizes. A database of typical construction and technical decisions seismic reinforcement were developed. UNCRD provided financial and technical support for demonstration projects on reinforced concrete frame, masonry, and frame panel buildings. The incremental cost of seismic reinforcement was shown to be between 3 % and 14 % depending on intensity zone, type of construction, number of floors, capacity, and ground conditions (Khakimov et al. 2007).

In Italy, a substantial contribution comes in the form of an overall risk management framework developed for retrofit prioritization (Grant et al. 2007). Some schools have now been assessed in Emilia-Romagna (Rodgers 2012). Portugal has demonstrated an important

innovation by incorporating school vulnerability assessment and retrofit into its ongoing modernization program. At least 330 public school buildings have been assessed and retrofits designed (Rodgers 2012; UNISDR 2012).

The Istanbul Seismic Risk Mitigation and Emergency Preparedness Project (ISMEP) (with loans from World Bank and EIB) allowed for retrofitting of 250 schools and reconstruction of 36 schools in 2007–2008 with 600 more undergoing assessment and feasibility studies. In 2009 the remaining 450 schools were slated for retrofitting.

South Asia: Bhutan has begun a nationwide vulnerability assessment of school buildings. The first phase, covering 5 of Bhutan's 20 districts, began in 2013, with funding from UNICEF.

In India there are several examples of large-scale seismic vulnerability assessments: In Gujarat a modified RVS was conducted for 153 schools following the 2001 earthquake (Rodgers 2012). In Shimla, SEEDS India took a stepwise approach: Step one was low-cost mass scale RVS of school buildings. From these, a smaller number were selected for simplified vulnerability assessment using limited engineering analysis. The highest-risk buildings were identified for detailed vulnerability analysis (SEEDS 2006). Retrofitting designs were drawn up for 20 schools and implementation carried out in ten schools. Guidelines were developed for retrofit and training of local masons and engineers and delivery of skill training. "Nonstructural mitigation plans" were carried out in 20 schools. An awareness campaign reached out to all 750 schools, including nearly 100,000 students, 7,500 teachers and local builders, engineers, and officials (SEEDS 2006). The Government of India's National School Safety Program plans to seismically retrofit more than 40 schools throughout the country as demonstration projects. The National Center for Peoples' Action in Disaster Preparedness (NCPDP), GeoHazards International, and others also carried out school assessment and retrofit programs.

Nepal has also made some strides in both vulnerability assessment and retrofit planning. There are an estimated six million children and 140,000 teachers at risk of death and injury in schools. In the Kathmandu Valley, 643 schools (1,100 buildings) have been inventoried and 378 (695 buildings) surveyed for vulnerability. Seventy-five percent are expected to be damaged beyond repair, in a scenario earthquake. A school day earthquake would kill 29,000 children and teachers and injure 43,000 (Dixit et al. 2013). The MoE has planned to retrofit 900 schools in the Kathmandu Valley over 5 years (Dixit et al. 2012). In Lamjung and Nawalparasi, vulnerability screening has covered 745 and 636 buildings, respectively, some with detailed assessments (Rodgers 2012).

In Pakistan, in 2008, the Aga Khan Planning and Building Services, Habitat Risk Management Program in Northern Pakistan, used retrofitting of four schools to demonstrate structural and nonstructural seismic retrofitting, to train builders and to train female village youth in mapping, land-use planning, and disaster management (INEE 2010).

Southeast Asia: There has been relatively sparse activity when it comes to seismic safety of schools in Southeast Asia. It may be that the frequency of cyclones and flooding and even the threat of tsunami precede thoughts of earthquake risks. It may also be that the rapid pace of development and the increasing numbers of new children being brought into school have led to natural prioritization of safe new construction rather than retrofit. In the Philippines, local authorities are responsible for school construction. However, assessment, design, and inspection functions are provided by Department of Education engineers who assist the principal during the procurement process. The Parent, Teacher, and Community Association and other community stakeholders are responsible for auditing procurements. Earthquake, typhoon, flood, and even volcanic ashfall resilience must often be factored in (INEE 2010).

East Asia: School seismic safety has been on the agenda in Japan for many years, but it is only since 2005 that 125,000 public school buildings nationwide have been assessed by the Ministry of Education (MEXT) (Rodgers 2012). Sixty-two percent of these were constructed before 1981, when the current anti-seismic code enforcement began. About 25 % of schools are considered safe, but 48,000 older school buildings were found needing assessment or retrofitting. 10,000 of these were found to be at high risk of collapse in expected earthquakes. The Ministry of Education raised subsidies for vulnerable school buildings from 50 % to 67 % in 2008 when 229 billion JPY was allocated to meet the new goal of retrofitting of all highest-risk school buildings within 4 years.

Oceania: School seismic safety is also on the agenda in New Zealand, where a walk through survey of 21,000 buildings at 2,361 public schools in 1998 triggered a follow-up investigation in 2000 (Rodgers 2012). A World Bank GFDRR project demonstrated school retrofit in six schools in two districts (2008–2009).

Summary

In the course of the past decade, an approach to all hazards and all aspects of school safety has emerged in both the literature and practice of global advocacy. The Global Alliance for Disaster Risk Reduction and Resilience in the Education Sector (led by UNESCO, UNICEF, UNISDR, IFRC, INEE, Save the Children, Plan International, World Vision) use the shared Comprehensive School Safety framework. The framework takes a multi-hazard approach and addresses the many different factors needed to address safe school facilities, school disaster management, and disaster reduction education. While seismic vulnerability (and related secondary hazards) to school buildings are naturally of concern to earthquake engineers and many others, it is important to fit this into an

all-hazard and comprehensive approach so that the solutions to seismic safety do not ignore coexisting vulnerabilities to cyclones, floods, and volcanic eruption nor conflated with the broader approach that also addresses disaster management and education (Global Alliance for DRRR in the Education Sector 2014).

Overall, the threat of earthquake damage to school buildings has not been sufficiently well appreciated. School safety issues have not featured in the major global campaign for increased school attendance (“Education for All” and the Millennium Development Goals). The full extent of the risk to school buildings and to students remains to be fully defined.

A global effort at mapping schools (by density of occupancy and quality of construction) in relation to seismic and other hazards has been proposed by the World Bank Global Facility for Disaster Risk Reduction and Recovery, to begin in 2014. The full impacts of earthquakes on the education sector cannot end with calculating the value of structural and nonstructural damage. The impacts on *children’s education* are almost entirely unmeasured. Research is needed to understand how educational outcomes such as enrollment, attendance, and achievement are impacted by earthquakes.

There are strong arguments that support giving school seismic safety increased priority and a higher profile. An initial step in raising the visibility of this issue was the adoption of school safety as one of the focal points for advocacy in preparation for the Hyogo Framework for Action 2005–2015 adopted at the World Conference on Disaster Reduction held in Kobe, Japan, in January 2005. The development of the Comprehensive School Safety framework in 2013 has begun to articulate how school facilities safety can be understood within the wider context that includes school disaster management as well as risk reduction and resilience education. As a post-2015 agenda for both development and disaster risk reduction are currently under consideration, it

continues to be extremely important to raise the profile of school safety. In preparation for this, child-centered organizations have formed a Global Alliance for Disaster Risk Reduction and Resilience in the Education Sector.

Based in part on the case studies (see entry “► [School Seismic Safety: Case Studies](#)”), it seems evident that low-cost, accessible technology and design exists with which to build new schools and to retrofit existing ones. A community-based approach holds great promise involving many stakeholders, including local buildings, masons, contractors, etc. Promising demonstration and large-scale projects in Nepal, India, Turkey (see entry “► [School Seismic Safety: Case Studies](#)”), Central Asia, and the Caribbean islands all provide strong experience to build upon for case studies.

Case studies also make clear that child rights advocates, parents, and seismic safety experts together, lobbying for school seismic safety, can be extremely effective in achieving policy change, as case studies of British Columbia and Bogotá (see entry “► [School Seismic Safety: Case Studies](#)”) show.

School seismic safety has been the subject of both research and policy since the 1933 Long Beach earthquake that spurred California’s landmark *Field Act*, requiring that school construction meet seismic safety standards. As both seismic risk assessment and building codes have progressed, so too have expectations for selection of performance standards. However, globally, the application of these standards and codes falls short in several major respects: community-built schools are frequently constructed using high-tech materials intended for engineered construction, without the corresponding understanding, training, or supervision; where building codes exist they are not known, understood, or consistently applied; and safe site selection is frequently skipped, and site-specific hazards are not factored in. Privately built schools are often exempt from the same standards of construction as public schools. The need for programs and people that bridge the available engineering knowledge with scalable on-the-ground national programs is significant.

In 2009, *Guidance notes on safer school construction* (INEE 2010) was published to synthesize and kick-start systematic guidance. An important global resource for documents to guide safe school construction was initiated by UNESCO IPRED, immediately after the Haiti earthquake (UNESCO IPRED 2010). This resource database endeavors to compile both building codes and the now numerous documents produced by NGOs or at the national level with standard designs for safe school construction, and in some cases with construction guidance.

The past decade has seen several relevant scientific papers suggesting methods for vulnerability screening (e.g., in Italy, Grant et al. 2007), and detailing approaches to seismic retrofit. The challenge is whether or not the guidance and the science are put into practice. The written record does not suggest that these approaches are yet systematic, are supported with training, are monitored, or are applied to both public and private schools. Community-built and un-engineered construction has been addressed in far fewer publications and has not specifically addressed school construction.

There have been a small number of significant programmatic efforts to support seismic safety. UNICEF’s regional office for Central and Eastern Europe and the Commonwealth of Independent States, with support from the World Bank and DIPECHO, has partnered with national governments in Central Asia and the South Caucasus to address school safety. Part of that work has included developing a broad regional framework for assessing and ranking school facilities based upon exposure and vulnerability to earthquakes and other natural hazards. Drawing upon INEE’s *Guidance notes on safer school construction*, UNICEF elaborated a list of 17 simple indicators that local experts could use as part of a rapid visual assessment of school facilities in order to identify schools at risk of heavy damage in seismic events.

In 2012, engineers in Kyrgyzstan localized this framework and carried out a national school safety assessment of over 3,000 learning facilities with USAID funding. They reported to the national government that over 80 % of learning

facilities were vulnerable to damage in seismic events and provided public access to the assessment through an online portal. Similar national assessment strategies are being piloted in Kazakhstan, Tajikistan, Armenia, and Azerbaijan.

Similarly, UNCRD (UN Centre for Regional Development) showcased community-based comprehensive school earthquake safety in selected countries of Asia Pacific. Under the program “Reducing Vulnerability of School Children to Earthquakes,” school communities carried out seismic retrofitting of their school buildings with expert guidance from Bandung Institute of Technology (ITB) in Indonesia. The retrofitting works in public schools were used for community awareness on earthquake safety through community visits in the school premises during construction time. Pilot school assessment and retrofitting in Fiji led to the National Disaster Management Office (NDMO) adopting school safety program under regular government that also developed seismic retrofit guidelines and mason’s training manual. Tashkent city government (Hokimiyat) in Uzbekistan appraised neighborhood associations on schools retrofitting programs and used school constructions for training of engineers on seismic safety.

The United Nations International Strategy for Disaster Reduction (UNISDR) launched the 2006–2007 biennial awareness campaign “Disaster Reduction Begins in Schools.” This was followed up in 2010 with the *Resilient Cities Global Campaign for One Million Safe Schools and Hospitals Campaign*. The 10-point checklist that 1,643 Mayors have signed on for, includes assessing and upgrading the safety of schools. These successes deserve praise but should not induce complacency. There is a long way to go with respect to school seismic safety.

Initial programs and guidance for safe school facilities have been provided by OECD (2004), UNCRD (2008), INEE/World Bank GFDRR/UNISDR (2010), and several other programs, with modest support of donors and lenders. These approaches experiences are now ripe for implementation at scale. These include regional hazard mapping and revision (where necessary), the potential for crowd-sourced

mapping of local hazards; enforcement of seismic building codes by national, provincial, and local governments; training of engineers and significant capacity-building efforts to train local masons and other builders; and invention of more innovative models for funding reinforcement of schools.

It is important, however, not to fetishize the safety of school *buildings* and to take care not to separate the safety of the community of users and educational continuity planning, which is not limited to the buildings themselves. Neither should the focus be solely on fatality prevention. There is much similar work to be done to prevent disability and injury especially by securing the contents of the buildings and to assure educational continuity. All-school, participatory school disaster management planning, local risk assessment and risk reduction, mastery of emergency response skills, and regular drills to practice and improve readiness are important. A culture of safety is necessarily multifaceted, and activism in one area encourages changes in consciousness, expectations, and demands.

The enthusiasm for making education accessible to all does not absolve duty-bearers from assuring that school is safe from infrequent but high-impact hazards such as earthquake and various secondary hazards. It would be an ironic and tragic result if the achievement of one Millennium Goal (increased school attendance) is marred by increased death and injury of young people, thus setting back the achievement of another Millennium Development Goal (reduction of child mortality).

Introduction

The case studies in this entry accompany the previous entry on School Seismic Safety and

Mitigation. They tell the stories of a variety of national efforts to improve school seismic safety. The contributors to the case studies are engineers and parents, social workers, and international development specialists. They examine policy, advocacy, vulnerability, and solutions. They contain observations about stepwise progress, motivation, political will, technical approaches, innovations, moderate successes, and long roads ahead. There are more stories to be added. The intention is to provide school seismic safety advocates with both elements of inspiration and way points on a road map with many options to consider.

The case studies and their contributors are:

Algeria – Djilali Benouar

Canada – Tracy Monk

China – Sanjaya Bhatia

Colombia – Omar Dario Cardona

India (Delhi, Shimla) – Manu Gupta

India (Uttar Pradesh) – Sanjaya Bhatia

Italy – David Alexander

Japan – Rajib Shaw

Nepal – Amod Mani Dixit, Jitendra Kumar Botendra, Ram Chandra Kandel, and Bishnu Pandey

Turkey – Marla Petal and Zeynep Türkmen Sanduvaç

USA (California) – Marla Petal and Rebekah Green

It is important to note that school *seismic* safety should not be isolated from school safety from disasters and climate change impacts in general. It cannot be considered responsible to approach the rights of children from our narrow professional silos. It is incumbent upon all advocates for children to see the matter from their point of view, that is, from the perspective of all of the physical threats to their right to survival and safety and from all of the threats to their right to education and development.

Similarly, key stakeholders in the seismic safety of schools (engineers, architects, builders) must make the effort to think not primarily about the *structures*, but rather about the people who

use the structures. The users must also have safe access and egress. For the users, infill walls that fall out of plane and unsecured nonstructural building elements or building contents are a far greater threat than their “minor damage” designation suggests. If the building is going to be one of the strongest structures in the community, then it may also need to be planned to be as a cyclone shelter or to double as a shelter for people displaced after an earthquake. In that case, water and supply storage and extra sanitation facilities have to be considered. And the job is not complete when the key is handed over. Buildings that do not come with a user’s manual and a school maintenance calendar stand little chance of being safely maintained. Thus, the concern for school seismic safety does not begin and end with the structures themselves, but must take a holistic approach and, of course, include the user community.

Algeria

Ninety percent of Algeria’s population of 30 million is concentrated in a band about 60 km wide and 1,200 km long along the Mediterranean coast on the African and Eurasian tectonic plate boundary. This region has repeatedly experienced moderate-to-strong earthquakes. During the twentieth century, earthquakes claimed at least 10,000 lives, injured about 27,000, and made about half a million homeless. In addition to building collapse due to earthquakes, considerable damage from liquefaction and landslides was observed.

School buildings have also suffered considerable damage in earthquakes, varying according to the period during which they were built: (1) those degraded through aging and lack of maintenance, built during the colonization era (1830–1962), account for about 30 % of the school building stock; (2) those built after independence, during the 1970s, with rapidly growing population and democratization of educational opportunity (when primary school became free and compulsory), when school construction accounted for the largest single item in Algeria’s budget, were designed and built without taking into account

seismic risk; and (3) those built with technical supervision after 1983 and the introduction of Algeria’s seismic building code in 1981.

Schools in Algeria are all state owned and were built by the government. The government adopted one typical structure for all schools that could be duplicated easily across the country. The standard architectural design of schools involves two fundamental elements: the classroom and the circulatory corridors. Classrooms are 7×4 m and circulatory corridors are 2.5 m wide. These are far from those of an ideal seismically resistant structure as recommended by Algeria’s own seismic codes. Other standard design elements also unfortunately reduce the resilience of these school structures.

Numerous reports show the deficiencies in design, construction techniques, and materials (poor quality of concrete) with respect to particular earthquakes at El Asnam (1980), Chenoua-Tipaza (1989), Beni Chougrane-Mascara (1994), Ain Temouchent (1999), and Boumerdes-Algiers (2003) (Bendimerad 2004). The following typical damage to school buildings was recorded in recent earthquakes:

- Rupture of staircases
- Destruction of joints
- Destruction of short columns
- Damage in Masonry
- “Pancake” collapse due to weak columns, overly strong beams, and heavy roofs composed of reinforced concrete slabs

Such damage causes enormous financial loss to the government. For instance, after the Boumerdes-Algiers earthquake disaster of 2003, 100 primary schools had to be rebuilt completely for the sum of US\$4.28 million and 253 rehabilitated for \$10.65 million. In addition, 12 junior high schools were completely rebuilt for the sum of \$10.28 million and 111 rehabilitated for \$20.85. Also, 10 high schools were rebuilt for the sum of \$21.42 million, and 58 were rehabilitated for \$12 million.

So far these destructive earthquakes have occurred after school hours or on weekends, and thus, no loss of life or injuries have been recorded

at schools in Algeria. This good luck may have made the government and the civil society alike less aware of the high vulnerability of the schools and partially explains why there has so far been no implementation of a Ministerial instruction dating from 1989 that required application of “technical expertise and the eventual reinforcement of all public buildings and in particular schools and universities.” Instead, the introduction of new materials such as reinforced concrete in the absence of proper seismic-resistant design, building codes, and enforceable regulations has increased the risk to structures and their occupants. Relatively minor reinforcements could reduce the potential for damage to these structures.

Canada

British Columbia’s (BC) west coast is Canada’s region of highest seismic hazard. Two-thirds of the province’s 3.9 million people live within the zone of highest risk. The region has experienced ten moderate-to-large earthquakes since 1870. In recent millennia, an earthquake on the order of the largest magnitude experienced globally in the last 100 years has struck approximately every 500 years. In addition to potential building collapse induced by ground shaking, significant damage from liquefaction, tsunamis, and landslides are expected.

Older BC schools were built from some of the most seismically vulnerable materials – in the early 1900s, unreinforced masonry and then, in the mid-1900s, non-ductile concrete frame. Thus, in many communities, the school might be one of the buildings at highest risk for earthquake damage. A formal risk assessment of all BC school buildings was initiated in June 2004 with the full report due in October 2004. Initial estimates from the provincial government suggest that 800 of BC’s schools might need some form of seismic upgrading.

In Vancouver, BC’s largest city with a core population of about 560,000 and a metropolitan population of about two million, a 1989 rapid seismic risk assessment found that 30 % of the city’s school buildings were at high risk of

experiencing structural damage in an earthquake, and 15 % were at moderate risk (Taylor 1989). Between 1990 and 2004, 11 schools have been upgraded, so if the current pace continues, this work would be completed in 2064.

While the seismic hazard facing schools in greater Vancouver is similar to that in Seattle, Washington, school safety has not been a priority on the Canadian side of the border. Indeed, differences in seismic hazard mapping techniques used by Canadian and US geoscientists may actually underestimate the risk to Vancouver schools.

The current National Building Code of Canada ranks buildings according to their priority as critical infrastructure. The higher the number assigned, the higher the priority. Average houses are assigned an Importance Factor of 1.0, schools are designated 1.3, and hospitals, police stations, and prisons are assigned 1.5. Schools – unless they are designated as post-disaster shelters – get a lower priority than hospitals, police stations, and prisons. Vancouver City Council is funding the seismic upgrading of community centers so that they could be used as post-disaster receiving centers. Due to the differences in funding sources, some community centers are being upgraded, while nearby schools, which might be less seismically resistant, are sometimes not.

In general in BC there is high awareness of earthquake risk. For example, the City of Vancouver has seismically upgraded its water supply system and bridges, and the electric utility, BC Hydro, is systematically upgrading its buildings and infrastructure, including dams. Even some provincially run liquor outlets have been seismically upgraded. With seismic safety so clearly on the policy agenda in many sectors in British Columbia, why have public schools received so little attention?

The answer is that in BC funding for public school seismic upgrades has been part of the capital budget of the provincial Ministry of Education. Local school boards oversee this work and must proactively request provincial funding for projects that they deem to be high priority. Advocacy work by one of the authors on behalf of Families for School Seismic Safety British

Columbia (FSSS) identified and tackled concerns with this funding system.

First, there was no district-to-district standardization of approach. Each local school district was individually approaching the issue of seismic safety for only their schools. FSSS pressed the government to unify the approach taken by centralizing expertise. The earthquake engineering community, through its professional association, the Association of Professional Engineers and Geoscientists of BC, is now advising the government on standardized, peer-reviewed methods for assessing and addressing seismic risk to schools.

Second, local authorities were concerned that informing parents of the seismic risks to local schools could cause panic and could be politically damaging. FSSS's and others' work has ensured that Vancouver parents are now well informed about the issue and are actively involved in trying to solve it. This process did not cause panic. Instead, bringing parents into the consortium has yielded an active and effective lobbying group.

Finally, there is the problem of setting priorities. The primary concern of school boards – quite rightly – is the day-to-day education of children. Seismic safety of a school building does not lead to improved education, so school boards have sometimes had difficulty making the issue a high priority. FSSS is trying to help public officials see school seismic safety as an infrastructure, public health, and human rights issue and to obtain new funding from outside of the Ministry of Education, that is, from provincial and national, authorize with mandates in those areas. The aim is that this work be seen as an infrastructure project for children and not perceived as competing for funding with their day-to-day educational needs.

Ultimately, the two basic human rights of children, to an education and to physical safety, should not be competing for the same funds. The expert community is now driving the initiative and the government appears to be listening. Many positive steps have been taken in BC, but there is much work left to be done.

China

Following the 2008 Sichuan earthquake in which at least 15,000 children lost their lives in schools, the Ministry of Education and the Ministry of Construction and National Development and Reform Commission (NDRC) jointly released the Design Instructions for School Planning and Construction after the Sichuan earthquake. These standards require that school sites are assessed before the schools are built in accordance with national regulation, performance objectives are determined by the country-level government, schools are built or retrofitted to meet performance objectives, and schools' furnishings and equipment are designed and installed to minimize potential harm they might cause to school occupants. The quality-monitoring bureau leads monitoring on the safety of equipment installation.

In Sichuan in the spirit of "building back better," the investigation, design, construction, supervision, inspection, and acceptance of school construction are conducted in line with relevant national construction standards. In Sichuan, steps were also taken to make sure that there are mechanisms to ensure that schools' maintenance is financed and executed. From 2000 to 2005 the first and second session of school renovation and maintenance was conducted. After 2006 a long-term mechanism for school building maintenance was put into place. MOE and UNICEF collaborated and prepared and revised the National Guidelines for Safe School Construction and Management and also collaborated to develop construction standards for kindergartens and preschools.

In 2009 the Ministry of Education (MoE) initiated a 3-year national "School Construction Safety Programme" to upgrade the safety of primary and middle school buildings all over the country with the aim of making schools the safest places in China. The program has several key elements:

- To screen and assess the quality of all school buildings across the country, to understand the qualities of buildings resistant to local disaster

risks, and to input the data and information of the assessment into a database

- To understand disaster risks in the regions where the schools are located, such as determining whether local disaster risks come from floods, landslides, earthquakes, or rainstorms threatening the safety of the school buildings
- To determine whether to repair, strengthen, or reconstruct school buildings that have not reached official standards based on the intensity of the identified disaster risks in the region where the schools are located
- To allocate funds and to start the construction work to upgrade the primary and middle school buildings that are at risk (International Recovery Platform 2010)

Colombia

The capital city of Colombia, Bogotá, is the most important political, administrative, economic, and cultural center of the country and has one million school children. Bogotá's population was estimated to be around 7.6 million in 2013. As a result of social investment over the past decade, more than 12 % live below the poverty line.

Among the most common hazard events affecting Bogotá are earthquakes and landslides. Although there has not been a severe earthquake in Bogotá since 1917, there is certainly the potential for one. Also, elsewhere in Colombia, 74 % of the schools in the cities of Pereira and Armenia suffered damage in the 1999 earthquake. Fortunately this occurred during the lunch hour, when no children were in the school buildings.

Several risk identification methods were put in place in the city prior to 2004. These include compilation of records of hazard events, generation of hazard maps, studies of physical and social vulnerability, and studies of environmental degradation. One of the means of reducing risk from earthquakes and landslides in Bogotá is the assessment of seismic risk of bridges, hospitals, and schools. This has become a core part of the city's economic and social development plan. Of these assessment programs, the best-known

is the Department of Education's effort to identify school seismic risk and to reinforce schools.

Much of the educational infrastructure in Bogota is more than 50 years old and does not meet minimal standards of safety. The Department of Education commissioned a systematic review of schools that ran from 1997 to 2003 (Secretaría de Educación del Distrito Capital de Santafé de Bogota 2000). This study covered approximately 2,800 buildings at 706 schools serving roughly 54 % of the student population in Bogotá. The other 46 % of the student population attends private schools and was not covered in this review. The review found that 434 of the schools presented high risk to students. Some 772 buildings at these schools fell into this category (16 %). The study also found that 60 schools had buildings in immediate and urgent need of reinforcement.

During the next city administration, from 2004 to 2008, after a detailed technical explanation on the need of schools' retrofitting, the city mayor decided to implement a retrofitting program of the 200 most vulnerable schools. A special risk analysis was performed on each building that was identified and prioritized. From this analysis, the structural reinforcement requirements were defined according to the seismic building code updated in 1998, with new special provisions for schools. The comprehensive improvement program had to be adjusted. Taking into account other technical, urban, economic, and environmental issues, many schools were not retrofitted: 67 schools were demolished and full restitution was made for a total of 107 new schools. This additional program was called the "50 Macro-schools plan" whose goal was to provide an educational infrastructure of maximum specifications and supplement the retrofitting and integrated improvement program. At the end, due to the costs involved in reducing vulnerability for 434 vulnerable schools, 201 schools were considered in critical condition according to risk studies that were conducted to prioritize and rank the schools. The reinforcement of these buildings had a cost about US\$ 200 million and the total program including the new schools was about

US\$ 430 million. Additionally, this program was based on the implementation of a teaching strategy to incorporate risk management into the culture. Both structural and nonstructural objectives were implemented to obtain a comfortable and safe school environment and a high-quality education service.

Assessing and reducing the risk to schools in Bogotá took place in a more general planning and management context. For example, zones of high risk of landslide, where no mitigation works are possible, are declared to be protected land. Human occupation is restricted in these areas as well as those considered at high risk to floods. In 2003 it was estimated that some 185,000 people lived in informal settlements in a total of 34,230 informal housing units. In Bogotá there are 173 illegal settlements that account for 14 % of the total land area. The city administration has developed a massive legalization program since 1995, thus reducing the number of informal settlements from 1,451 to its current number, an eightfold reduction in less than 10 years.

Nevertheless, as much as 60 % of the population of the city lives in informally constructed dwellings. While most of these are located in legal settlements, they still represent a challenge to seismic safety. The year 2000 land-use master plan for Bogotá contains hazard and risk maps that determined land use, details of special treatment for high-risk areas, and arrangements for issuance of building permits, as well as protection plans for utilities and services. The city also relies on community-based networks to control illegal land occupation and has developed a large-scale relocation program for families living in high-risk conditions.

The city of Bogotá has disaster risk reduction at the center of its planning process, and in this context school seismic safety ranks very high. Having diagnosed the scale and urgency of the problem in Bogotá, steps were being taken to reinforce the most hazardous school buildings. The challenges the city still faces include completing the program, making the retrofitting of the second priority group of vulnerable schools, extending its school safety program to private schools that cover nearly half the school-aged

population, and accelerating the rate of school reinforcement to improve the safety of children and teachers. Bogota has had different governance problems during the last two administration periods. Unfortunately, two mayors have been removed or suspended by the national general attorney due to corruption and inefficiency. Due to these situations and perhaps changing priorities in risk management, the school safety retrofitting program was not continued.

India: Delhi

NGO partners SEEDS and GeoHazards International (GHI), working with the Government of Delhi, demonstrated earthquake nonstructural risk reduction in a public school. The school welfare committee comprised of faculty, staff, and local community members learned to identify the nonstructural building elements and building contents that could fall, slide, or collide during a likely Delhi earthquake, as well as fire and evacuation hazards. They were exposed to simple low-cost techniques for reducing these risks (moving some items, fastening others) and came up with innovative solutions of their own. The logic of regular fire and earthquake drills became readily apparent to these new stakeholders. A handbook for schools on nonstructural risk reduction developed by the NGO partners and published by the Government of Delhi provides a new resource for generalizing these lessons.

India: Shimla

A small-scale demonstration project for school retrofit was carried out by SEEDS of India and GeoHazards International. Structural assessment of school buildings was carried out using a filtering method: The first step was low-cost mass scale Rapid Visual Assessment Survey of school buildings for potential seismic hazards. Based on these surveys a smaller number were selected for Simplified Vulnerability Assessment using limited engineering analysis. The highest-risk

buildings were identified for detailed vulnerability analysis. Retrofitting designs were drawn up for 20 schools and implementation of retrofit carried out in 8 schools. Guidelines were developed for retrofit and training of local masons and engineers and delivery of skill training. “Nonstructural mitigation plans” were carried out in 20 schools. An awareness campaign was designed to reach all 750 schools in the region including nearly 100,000 students, 7,500 teachers, and local builders, engineers, and officials (SEEDS 2006).

India: Uttar Pradesh

There are 23.5 million children attending school in this moderate-to-severe seismic risk zone. As part of the Education for All campaign, the State Government of Uttar Pradesh constructed 82,000 additional elementary school classrooms and 7,000 buildings in 2006–2007. To ensure seismic resilience of the buildings, UNDP provided earthquake engineers who examined the blueprints for the schools and modified the design to integrate seismic resilience. The marginal cost increase of 8 % to assure seismic safety was funded by the government.

For effective implementation of the new modified designs, training and orientation programs were initiated by the government, supported by the local UNDP office, building the capacity of 40 architects, over 200 engineers, and over 10,000 masons. To ensure transparent monitoring, the designs were widely circulated to the local communities where the schools were constructed, so they could monitor the quality, along with support of departmental engineers. To complete the safety of the schools, school-level safety committees were established, school emergency plans developed, and mock drills became a part of the school program.

In 2006–2007 the Elementary Education Department proposed to integrate earthquake-resilient design into all new school buildings. To prepare for this, one design of primary school buildings and two upper primary and three additional classroom designs were prepared with

detailed construction manuals. The disaster-resilient measures added 8 % to the construction costs. To cope with the massive scale of the project, a cascading approach prepared 4 master trainers for each of the 70 districts. These individuals in turn conducted trainings for 1,100 fellow Junior Engineers and Education Officers. Ten thousand masons were also trained. This program ensures that *every new school will be a safe school*. The problem of preexisting stock of 125,000 unsafe school buildings in need of retrofit remains to be tackled (Bhatia 2008).

Italy

Of the 8,102 municipalities in Italy, all are regarded as “seismically active.” Up until 2003, 2,965 of them (representing 40 % of the land surface and 45 % of the population) were considered “highly seismic” category. As a result, new construction in this category must observe stringent anti-seismic building codes. Subsequently, a more sophisticated classification was introduced, based on a 50-year recurrence interval and local estimates of peak ground acceleration (PGA). This had the effect of increasing the areas classified as highly seismic. Whereas in previous classifications, some municipalities were effectively regarded as aseismic, that is no longer the case and all 8,102 are now considered to be in a seismic zone to a greater or lesser extent. Italy bases its seismic classification on historical records and calculated return periods. Where these are a poor reflection of seismic hazard, it can underestimate the earthquake threat. Hence, severe damage occurred in northern Emilia and southern Lombardy in the earthquakes of May 2012, an area that had not had a major seismic disaster since 1574.

Several hundred municipalities are faced with the highest seismic risk in the Strait of Messina (including eastern Sicily) and southern Calabria (the Aspromonte) areas. The Apennine Mountains, which form the “backbone” of the Italian peninsula, are, in a tectonic sense, divided into blocks, which means that seismicity varies significantly from one locality to another. However, the vulnerability of buildings, including schools,

is almost universally high: modest local taxation revenues inhibiting retrofitting and maintenance. The largest seismic event of the past century remains that in Avezzano, in 1915.

An event that for Italians most encapsulates the seismic risk to schools was that of 31 October 2002 at 11:40 a.m. where in the Apennine town of San Giuliano di Puglia (population 1,195), the infants' school collapsed onto a class of small children (Augenti et al. 2004). Twenty-six small children and three teachers were crushed to death, and 35 children were rescued and lived. The building had been constructed with regional development funds in the early 1960s and had had its roof renewed a year before the earthquake. Evidently, the roof, of reinforced concrete with a ring beam, was too rigid and too heavy for the underlying structure, a concrete frame building with hollow-brick infill. There were signs that the quality of the cement was poor and the reinforcing steel was not used as it should have been. Moreover, despite mounting evidence that the Molisan Apennines are significantly affected by periodic earthquake activity, the revision of local building codes to take account of the new data on seismic risk cannot be applied as easily to existing structures as it can to ones that are about to be built (Augenti et al. 2004, p. S258).

The school at San Giuliano di Puglia succumbed because it contravened simple, well-known laws of dynamic response in structures affected by seismic acceleration. Inertial forces applied to a heavy roof sitting upon a weak frame structure amount to a recipe for tragedy.

Consider the schools of the Lunigiana, a surprisingly remote mountainous area of northwestern Tuscany. The Lunigiana has a sparse and dispersed population. Children attend elementary schools in the villages and secondary schools in major population centers, which they reach by bus or car. Many of the school buildings were constructed in the 1950s and 1960s to cater for the postwar population boom, and, in a rural area of relative economic stagnation, they have neither been built to be fully anti-seismic nor retrofitted. Indeed, in the minor population centers, they are decidedly dilapidated, nor do their staffs seem to have much interest in repeatedly

practicing evacuation drills. Yet the area awaits a magnitude 6 earthquake, which it is predicted may kill up to 120 people and injure more than a thousand. How many of them will be school children? This situation is typical of the seismic risk that affects highland Italy.

Elsewhere in Italy, much more progress has been made. The civil protection departments of several regional governments have introduced comprehensive *Scuola sicura* (safe schools) programs, notably in the northern regions of Lombardy, Piedmont, and Emilia-Romagna and in the autonomous Region of Sicily. The programs involve a combination of structural measures and school disaster management efforts, such as evacuation drills and lessons in civil protection. In many of the major cities, fire brigades and volunteer civil protection services are heavily involved in the programs, with public-private partnerships supporting attractive safety literature for school children.

Despite these developments, as in other seismic countries so in Italy, the building stock of schools continues to age and the civil protection educators must fight against the indifference of teachers, principals, and administrators. In many respects, mass mortality in Italian schools during recent seismic events has been avoided mostly by the lack of major earthquakes during school hours, a situation that will not prevail forever. Given an overwhelming need to upgrade the seismic performance of schools in Italy, the response of the national government has been to rank the buildings in terms of the deficit between design requirements (a function of the rules that prevailed at the time they were built) and the latest assessment of peak ground acceleration (PGA). Priority funding is given to those schools that have the greatest "PGA deficit" (Grant et al. 2007). However, the problem of unsafe school stock is simply too expensive to solve in the short to medium term.

Japan

In general, Japan is understood to be a leader in evaluating seismic risk and in implementing building codes for seismic-resilient construction.

Two publications available in English are MEXT's school seismic retrofit handbook (MEXT 2008a) and school nonstructural reference book (MEXT 2008b). In addition to high seismic performance standards for schools, following the 1995 Kobe earthquake, Japan also began providing guidance for mitigation of hazards due to building nonstructural elements and contents in schools. Nonetheless, the East Japan earthquake and tsunami [of 11 March 2011, with magnitude 9.0 earthquake off coast of East Japan], destroyed 6,284 in the affected region with different damage levels. Most of these were affected by tsunami waves, rather than earthquake. This was due to the location of the school buildings [proximity to coastal areas], the layout and structure of the buildings, and the subsidence of local tsunami retention walls. At the immediate aftermath, some schools [with higher stories] were used as temporary evacuation sites, and later people were rescued by helicopters. In some schools, located in higher ground, people took shelter, which lasted till 6 months in some cases, which caused serious disruption of school education.

The disaster pointed out several dimensions of role of schools and disaster education: (1) Schools can play an important public infrastructure of the community; however, the structural safety of the building needs to be linked to operational [including supplies of emergency kit] and locational issues. (2) School-community linkage is an important element, and local communities played an important role along with school teachers for the management of the evacuation sites. (3) While it is unavoidable to use the school as shelter, the continuity of education in emergency is a crucial issue. (4) School-based community recovery emerged as an effective concept, where the reconstruction of school building was linked to enhanced community cohesion (Shaw and Takeuchi 2012).

Nepal

A risk estimate for Kathmandu Valley, the economic, political, and technological hub of Nepal,

based on a scenario earthquake similar to the 1934 Bihar-Nepal earthquake, suggests that more than six million children and 140,000 teachers are at risk in schools (Bothara et al. 2002). A survey of 900 public schools in greater Kathmandu Valley estimated that more than 75 % of school buildings would suffer severe damage beyond repair (estimated at US\$7 million), and other 25 % would suffer repairable damage. In the absence of intervention, an estimated 29,000 children could be killed in their schools. With intervention 24,000 of these could be saved and buildings protected (NSET 2000).

A more recent assessment of school buildings in other parts of the country shows that more than 9,000 school buildings, more than 10 % of the total in Nepal, would suffer partial to complete collapse, resulting in very high casualties.

Most Nepalese school buildings are community built, by local craftsmen who have no formal training and are often illiterate. Technically trained people are not part of this process, unless it is funded by the government. Construction is characterized by the high degree of informality. The local availability of the construction materials, such as fired or unfired bricks, stone in mud mortar, and timber, controls the construction process. The use of modern materials such as cement, concrete, and steel bars is limited by affordability and accessibility and is confined to urban areas and areas accessible by transport.

In Nepal, there is no mandatory policy to control school design and construction. While some schools are supported by international donor agencies and/or the government requires design/drawing details, many are directly constructed by the communities without standard design criteria or technical supervision. Likewise, site-specific hazards are also not considered during the design and construction. Some design details are available, but they may not be entirely suitable for specific sites/locations. At most local levels, people lack the capacity to understand and implement the earthquake-safe construction method.

Low budgets for most school construction and lack of awareness and knowledge on the part of

graduate engineers of traditional and informal construction methodology result in most school buildings lacking earthquake resilience.

The National Society for Earthquake Technology in Nepal (NSET), a national NGO, conducted a program to strengthen existing school buildings and promote structural as well as nonstructural components of the school buildings for seismic safety, leveraging the decentralized, traditional, and informal approach to construction (Bothara et al. 2004). This program involved craftsman training, technology development and transfer, and community awareness raising. Many local masons became master masons. On-site master masons worked in residence, supported by visiting engineers with far-reaching effects. Shake-table demonstrations of typical versus seismic-resilient construction impressed communities with the effectiveness and feasibility of seismic-resistant measures. By raising awareness in schools, the entire community is reached because lessons trickle down to parents, relatives, and friends.

The approach developed took into account sociocultural and economic issues, with outreach to all stakeholders – school staff, students, local community, local clubs, and the local and central government. They have all been involved in the process so that they become aware of the risk and support the solution. School building construction was taken as an opportunity to train masons and to transfer simple but effective technology to others in the community, including house owners.

Following this approach, NSET retrofitted more than 40 schools, mostly of unreinforced masonry buildings. The program was found successful in transferring technology to local craftsmen who were quite keen to learn about the complete process and to adopt the technology. These masons became the propagators of the safety message in the vicinity of these schools and the replication of earthquake-resilient construction. The long-term sustainability of these impacts has yet to be assessed, but NSET's experience shows that seismic retrofitting and earthquake-resistant new construction are both affordable and technically viable.

Turkey

Turkey has more than eight million children attending schools in 64 provinces in the first- and second-degree seismic risk zones. The 1999 Kocaeli (moment magnitude Mw 7.4) and Duzce (Mw 7.2) earthquakes with approximately 20,000 fatalities raised awareness of the school safety question, and the 2002 (Mw 6.0) Afyon-Sultandagi and 2003 Bingöl (Mw 6.4) earthquakes kept awareness high.

During the 1999 earthquake in Kocaeli, 43 schools were damaged beyond repair, and 381 sustained minor-to-moderate damage. School was suspended for 4 months causing major disruption to the lives of families and children. In Istanbul, 60 km away, there was damage at 820 of the 1,651 schools. Damage at 131 of these sites necessitated at least temporary school closure. Thirteen were immediately demolished, and another 22 were later slated for demolition when retrofitting proved too costly. Fifty-nine schools were strengthened and 59 repaired.

In the Bingöl earthquake of 2003, out of 29 schools in the affected area, 4 school buildings collapsed completely, 10 were heavily damaged, 12 slightly or moderately damaged, and 3 undamaged.

Public schools in the Kocaeli earthquake fared better than residential buildings and private schools. Had children been at school during the Kocaeli earthquake, far fewer would have lost their lives. The fatality rate in residential buildings in the Kocaeli earthquake was 1.5 % in heavily damaged buildings and 16.5 % in totally collapsed buildings (Petal 2009). Similar damage in higher occupancy buildings of the same type would cause higher fatality rates. In the single example of the school dormitory in the Bingöl earthquake where 84 children died, the fatality rate was 44 %. Average risks are theoretical and don't occur. Instead, the reality is that either the school is not occupied and no one dies or it is occupied and the fatality rates are high, and the tragedy is wholly unacceptable.

There is much that is right with school construction in Turkey. As a result of an assigned

importance factor of 1.5, public schools are designed to withstand a 50 % increase in earthquake design loads. Schools have regular symmetrical structural designs, and those that are only one or two stories have fared well, for the most part meeting standards for life safety, if not continuous occupancy. The lethality of school buildings is almost entirely attributable to shoddy construction and is particularly lethal in taller buildings that may also have design defects.

For decades all public construction was under the authority of the Ministry of Public Works and Settlement. Earthquake building codes on the books since the 1930s were updated most recently in 1976 and 1998, yet the existence of these laws has not guaranteed the safety of construction. The reasons are numerous.

Beyond an undergraduate or graduate degree, there have been no independent or nonacademic professional qualifications, proficiency standards, continuing education requirements, or licensure for architects or engineers nor any qualifications for building contractors. There are also no guidelines for reliable and systematic building inspection during construction. Penalties for noncompliance with building codes are beset with bureaucratic and social impediments and often are simply not applied. Legal liability in some future event with low-frequency occurrence can hardly be a deterrent with so many to share blame. Public construction has also suffered from a standard (though not legally required) preference for the lowest bid in public tenders. The civil service employment system also lacks proficiency standards and qualifications for professional staff; so at the local level there is a wide variety in the capacity for project supervision and control. Wage and salary levels are low, and there has been opportunity for both favoritism and corruption. There are no ombudsman or advocacy services to support consumer whistle-blowers.

Istanbul provides a dramatic example of three overlapping tasks:

- Immediate response to damages caused by the 1999 earthquake

- Implementation of a comprehensive retrofitting and replacement for seismic risk mitigation
- Follow-through on an ambitious program of school expansion and construction initiated to respond to the acute shortage of class space occasioned by three additional years of compulsory education enacted in 1998

After the 1999 earthquake, the responsibility for school construction was shifted to the Ministry of Education's Division of Investments and Facilities (DIF). In turn, DIF appointed consultants from the private sector to oversee the new facility design and construction. DIF also developed standard designs for the new facilities, and new school construction was financed by a combination of government funds and charitable contributions raised by not-for-profit foundations. New construction and procurement laws also went into effect; however, the cumulative impact of these changes and pressures is not yet known (Gülkan 2004).

In Istanbul of all projects the highest priority is given to regional boarding schools, then to schools in the 12 highest-risk districts, and to those in proximity to the Marmara seacoast. The overall mitigation and retrofit effort targets more than 1,800 buildings that constitutes the 80 % of stock predating the 1998 Building Code. This ambitious program is budgeted for US\$320 million (Yüzügüllü et al. 2004).

An additional problem in Turkey is that awareness of nonstructural hazards remains low. Classroom doors often open inward and shelving and laboratory equipment remains unfastened. However, concern that children advised to "drop, cover, and hold" might be injured by flimsy wooden desks led to production and distribution of 80,000 steel desks to more than 500 schools in the most vulnerable areas.

Schools are a well-distributed means of public education, and children can play a leading role in the dissemination of public safety messages. Thus, Professor Isikara, former head of KOERI, a major earthquake research institute in Istanbul, toured the country visiting schools, becoming known as "Grandpa Quake," and produced the

first children's books and popular educational and rap music cartoons for earthquake awareness. Both the Istanbul Governor's Office and KOERI's newly established Istanbul Community Impact Project (ICIP) produced handouts distributed to all school children. Schools also received books and CDs. At the national level an introduction to natural hazards was integrated into the primary school curriculum in Environmental Studies in 2002. Annual school-wide earthquake drills and preparedness and remembrance activities were initiated on 11 November 2001, to coincide with the Duzce earthquake anniversary.

Between 2001 and 2003, a cascading model of training and instruction called "ABCD Basic Disaster Awareness" was implemented by KOERI's Istanbul Community Impact Project. A curriculum was developed to address specific assessment and planning activities, physical risk reduction, and response preparedness measures to be taken prior to a disaster. This was a significant reorientation from previous "awareness" programs that began with what to do "during the shaking." A single full day of instructor training for 3,600 teachers was provided in collaboration with the Ministry of Education Provincial Directorates and outside donors. These teachers in turn communicated with 121,000 school personnel and through them with 1.68 million school children as well as with 700,000 parents. The project established an Internet-based monitoring system to monitor dissemination. Based on the success of this project, almost a decade later an even more ambitious scale-up was attempted.

In 2010 the Ministry of National Education is committed to taking the program nationwide with technical support from Risk RED, in a follow-up project supported by the American Red Cross. A distance-learning self-study curriculum was developed consisting of 1 course (10 lessons) in household disaster preparedness and 1 course (9 lessons) in school disaster management, with the goal of reaching 25,000 school-based instructors (Petal and Türkmen 2012). During the first year of deployment of the courseware in 2012, more than 79,000 MoNE employees completed one or more lessons. More than 65,600 users completed the School Disaster and Emergency

Management Course and more than 50,000 passed the final test. Almost 50,000 users have completed the Individual and Household Disaster Preparedness Course and more than 40,000 users have passed the final test. There were a total of 114,700 course completions, 92,800 final tests passed, and more than one million lessons were successfully completed by users. Within the first year, active users completed an average of almost 15 lessons each (Petal and Türkmen 2012).

In 2005, a loan to implement the Istanbul Seismic Risk Mitigation and Emergency Preparedness (ISMEP) was funded by the World Bank and European Investment Bank, to help prepare Istanbul for a probable earthquake in the Marmara Region. The project had broad aims to enhance the institutional and technical capacity of emergency management-related institutions, raise public awareness, assess priority public buildings for retrofit or reconstruction, and support building code enforcement (www.ipkb.gov.tr). "Component B" addressed seismic risk mitigation for priority public buildings. This included a feasibility study for retrofit of 1,128 education buildings on 796 school sites. Of these, 506 were strengthened and 148 were reconstructed. At the time of completion of the project, further 34 were slated for retrofitting and 27 for reconstruction.

USA: California

In 2008, seismic safety advocates in California launched the first Great Southern California ShakeOut. The now annual event has grown to include five western states and several central US states and has been conducted in cities in five other countries. In its first year four million children and adults participated through 207 school districts plus almost 750 individual schools (Risk RED 2009). In 2013 there were more than 9.6 million participants in the Great California ShakeOut drill. Globally there were almost 25 million registered participants in similarly inspired Great ShakeOut Drills. Of these almost 75 % were school-based participants (Earthquake Country Alliance 2013). This regular public

awareness event has heightened interest and concern in safe school facilities. With 3.6 million children enrolled in 262 public school districts in seven counties in Southern California, a major earthquake in the region could cause an unprecedented catastrophe for schools, children, and teachers.

School seismic safety has been a policy and a community concern in California since the 1933 Long Beach earthquake, and school emergency planning has been required statewide since 1984. With 75 years of public policy leadership to support school safety, new school construction standards are higher than those for regular buildings and come close to assuring life safety. An advice regarding non-structural mitigation measures (fastening furnishings, etc.) has been in place for 20 years and requirements for such mitigation have been in place for 10 years.

The 1933 Field Act implemented immediately after the Long Beach earthquake that year required that schools be built to 15 % higher performance standards than normal construction. In 1938 the Garrison Act required examination and improvements to pre-1933 construction, but went unenforced until 1968. The Uniform Building Code enacted in 1976 is now the current standard for safe school construction. The Field Act has been hailed as a high point in school seismic safety and California schools are considered the safest in the United States. Some school facility managers feel that its requirements are too stringent and too costly, and many seismic safety advocates feel that it does not go far enough. The Act requires that structural plans be prepared by licensed structural engineers and approved by an independent state agency (the Division of the State Architect (DSA)). Schools have continuous on-site inspection (rather than periodic), by a DSA-approved project inspector. Project architect and engineers must perform construction observation and administration, and a final verified report must be filed by the project architect, engineers, inspectors, testing labs, and the contractor (State of California, DSA 2007, 2009).

In 2007 the California Seismic Safety Commission found that: (1) The cost of compliance

with the Field Act is incremental and minimal. (2) Timeliness, consistency, accuracy, and communication are being improved by the Division of the State Architect. (3) The exemplary performance of school buildings is directly attributable to the stringent seismic design provisions, plan review, field inspection, and testing required by the act and which go beyond the standard building codes. (4) All public schools should be covered. A 2009 study reported that in the four major earthquakes since the Field Act, there have been no public school collapses. The construction to Uniform Building Code, the special enforcement and quality control provisions, an oversight by the Office of the State Architect, and the 2003 publication guiding mitigation of nonstructural hazards are all judged to be successful. Nonetheless, the work is not yet complete.

In 1999 Assembly Bill 300 required desk assessment of 9,659 pre-1978 school buildings. The final report based on woefully incomplete records was released in 2002 and found 7,537 potentially vulnerable buildings requiring detailed seismic evaluation. The cost of retrofit was estimated at \$4.5 billion (State of California 2002). Due to fear of planning and financial implications, details were not released to the public. In 2005 an investigative reporting series by California Watch finally achieved this (Risk RED 2009). In 2011, 20,000 uncertified projects were released on an interactive map (California Watch 2011).

A review of school seismic safety in California identifies four remaining areas of concern:

- There are still some 7,537 school buildings in California constructed before 1978 that are of questionable safety.
- Portable classrooms, which may account for one-third of all classrooms in California, may be particularly hazardous if not properly supported and fastened.
- Private schools are not currently required to meet these same construction standards as public schools.
- Nonstructural mitigation measures continue to require consistent application to protect children and adults from both injury and death.

- Each school district and private school is strongly recommended to conduct its due diligence and report on these issues transparently to parents, staff, and students, so that collective action can be taken to address these serious vulnerabilities. Neither fear nor California's persistent financial crisis in the education sector should be acceptable excuses for inaction (Risk RED 2009).

Summary

Most of these case studies have focused on the primary importance of safe school facilities, through both standards for new school construction and strategies for school vulnerability assessment and planning for retrofit and replacement. While sound earthquake engineering expertise is fundamental to advocacy, communications, planning, and execution of these efforts, it is also important to retain the perspective of the primary beneficiaries: children, teachers, and school communities. This necessitates going beyond the obvious: site selection, design, and construction. As some of these case studies indicate, it is also important to consider nonstructural mitigation, ongoing maintenance, safe access to school, school function as temporary emergency shelters, and even structural awareness education and the use of construction as an educational opportunity for children and communities. By taking this wider (and multi-hazard) view, the focus on safe school facilities overlaps with both ongoing school disaster management and with risk reduction education.

Elements.

Introduction

Seismic evaluation of a construction has to include, with a given level of accuracy, the interaction phenomena between (1) soil,

(2) foundation, (3) structural part of the construction to be intended as the part in elevation, and (4) nonstructural part to be intended as a part of the construction with minor or no task to the structural capacity.

From a conceptual point of view, it could be easy to assert the following principle:

the seismic evaluation of a construction has to be performed based on 1) the definition of Structural Resisting System (SRS) 2) a proper model implementation of the SRS 3) a proper analysis of the SRS.

Given that the previous principle could resolve the problem, the SRS verification remains one of the goals of the analysis process: it can be pursued with a probabilistic approach (ATC 58 2012) (1) defining the required performance (2) based on the predictable loss (direct and indirect) consequent to a given seismic event.

A general approach, in which the strategy can be framed, is the performance-based approach that (1) defines a given number of performance levels (PLs), (2) chooses a seismic level for each PL, and (3) requires a given performance for each PL. Examples of PLs are operational, immediate occupancy, life safety, and collapse prevention.

The performance-based approach delegates the applicator of it the definition or selection of the most appropriate tools to be applied for the (1) identification of the resisting system (RS), (2) structural analysis (modeling included), (3) capacity definition, and (4) verification.

The first step (RS identification) is not an easy task: the RS includes the soil and the construction that on the other hand can be split in structural and nonstructural elements which are not supposed to have any role in the global resistance of the construction with regard to neither of the so-called vertical loads or of the horizontal loads such as those that schematize wind and seismic actions.

The nonstructural elements, having no role in the seismic capacity, are generally considered as additional weight to be included in the mass evaluation, neglecting the structural interaction between them and the structural resisting system.

For many of the nonstructural elements, the absence of interaction can be considered realistic so that they can be considered as attached elements (from which the name attachment derives) that having a proper structure (mass, stiffness, structural capacity) have to be verified with regard to the seismic action transferred to them (from the resisting system).

The attachments (as previously introduced) are objects with their morphology so that they can be schematized with either continuous or discrete models opportunely connected to the structure they are attached to. Examples of attachments are (1) furnitures, (2) technical systems, and (3) art objects of a museum.

If the structure-attachment interaction is negligible as well as the soil-structure interaction, a cascade procedure can be adopted evaluating the seismic action (in terms of time histories or response spectrum) (1) at the base of the structure in elevation and then (2) transferring it at the points to which the nonstructural element is attached.

The cascade procedure, not considering the primary (SRS) and secondary (attachments) systems as a whole entity (PS system), cannot be adopted when the two systems are tuned; that means their periods are similar and the attachment could be acting as a tuned mass damper (TMD) for the primary system.

The seismic analysis of the attachments can be performed by means of different strategies (Villaverde 1997; Chen and Soong 1988) among which linear and nonlinear analyses can be included: the PS system can be analyzed as a global system with an evident computational effort.

The need of efficient and accurate methods to analyze the PS systems inspired methodologies (Igusa and Der Kiureghian 1985a, b) based on (1) modal synthesis, (2) perturbation theory, and (3) random vibrations.

The decoupling of the secondary system (from the P system) allows the evaluation of the seismic action in terms of Floor Response Spectra whose approach is similar to the approach that governs the decoupling between soil and structures: a Response Spectra is defined and applied at the

base of the structure, including in it the effect of the propagation of the seismic action in the soil. Similarly, a spectra (FRS) is defined at the base of the attachment, including in it, with a cascade procedure, the effect of the propagation of the action at the soil (at first) and, subsequently, at the elevation structure.

The definition of a Response Spectra at the base of the attachment solves the problem since the attachment can be analyzed with traditional methodologies that are, for example, Seismic Modal Analyses or Time Histories Analyses based on acceleration histories compatible with the given Floor Response Spectrum.

Usually the effect of the propagation of the seismic event (from the soil to the attachment) is performed considering a linear behavior of the primary structure: this is supposed a realistic assumption for new conceived structure when operational and immediate occupancy PLs are considered.

The linear structural behavior of the principal system could be considered as nonrealistic in some cases, where the system's nonlinearity could produce effects (on the attachment) more severe than those evaluable with a linear behavior assumption (Chaudhri and Villaverde 2008).

The attachments, as discussed so far, are secondary elements that do not give any contribution to seismic resistance of the primary system and, in these terms, can be classified as secondary nonstructural elements (NSEs) to be distinguished from the secondary structural elements (SEs) that have a negligible role in supporting the seismic action but can have a specific role in transferring the vertical load to the foundation system.

Secondary elements, either attachment (secondary NSEs) or structural elements (SEs), are both systems having their structure, opportunely linked to the primary structure: they have to be adequately modeled in order to be analyzed with the strategies common to the seismic branch, such as (1) static analyses (linear and nonlinear), (2) modal response spectrum analyses, and (3) time domain analyses either linear or nonlinear.

Morphological and Phenomenological Aspects Versus Modeling and Analysis

Depending on the structural resisting system typology and the construction usage, the NSE typology can be wide (see Fig. 1, for the building case) and their taxonomy can be found in Taghavi and Miranda (2003) where a comprehensive data-base of nonstructural components is presented covering different aspects such as, among others, cost information from which is deducible that the structural cost of a building could be not relevant with respect to the global cost: the office buildings structural costs, even if relevant, are only 18 % of the total cost of construction that can be split in

cost of (1) structural elements, (2) secondary structural elements, and (3) nonstructural elements such as the contents are. The cost of the nonstructural elements can be estimated to reach the 70 % of total construction costs if the hotel buildings are concerned, while it is lower in office buildings (62 %) and hospitals (48 %) where contents (such as medical equipment) can be estimated to be 44 % of the total cost.

Economic loss due to seismic nonstructural damage can be relevant: during the 1994 Northridge earthquake, the nonstructural damage was (Kircher 2003) about 50 % of the global building damage which was estimated to be \$18.5 billion.

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Fig. 1 Typology of building nonstructural elements. Reproduced from FEMA 74 (2005)

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Fig. 2 Principal rigid body mechanism

Most of the NSEs have limited seismic performance because they are not properly attached to the primary structures, so that, depending on their slenderness, they can (see Fig. 2) (a) topple over, (b) slide and topple, and (c) slide. The loss of capacity of the NSEs or their connections can cause damage to other equipment (see Fig. 2) and injury to people, so careful attention has to be paid to the design of the connection (see Fig. 2).

Unlike the old conceived NSEs, the new-generation elements can have a good seismic performance, thanks to the wide range of connections that can be adopted to link the NSE to the structure. Depending on the case at hand, the design can include (1) seismic joints opportunely designed to accommodate seismic displacements, (2) seismic isolators to reduce the acceleration level, and (3) dissipative device to reduce the level of acceleration, velocity, and displacement.

So the new-generation NSEs cannot be conceived without an adequate strategy for the connection design, an example of which is reported in Fig. 3 where the case of a machinery (for cement production) mounted on a steel structure attached on a reinforced concrete building has been reported: dissipative devices have been introduced at the base (of the steel structure) to

reduce the seismic action on both the machinery and building.

Referring (see Fig. 3) to the previously introduced example (where the equipment can be considered as an attachment of the primary structure), the following indications can be given for the seismic analysis:

1. If the NSE is rigidly connected to the structure and its mass (M_{NS}) is not negligible with respect to the building mass (M_S), a global analysis of the PS system is required. In case of modal spectra time history (TH) analysis, some approximation in the damping definition is needed due to the different damping of the attachment (steel structure) with respect to the reinforced concrete structure. More appropriate step-by-step TH analyses can consider the element damping, properly modeling it by means of dashpots when *nonclassical* damping is present.
2. If M_{NS} is negligible with respect to M_S , but the NSE period (T_{NS}) is close to structural period (T_S), the so-called *tuning* happens and a global analysis of the PS system is required, not excluding positive effect.
3. If M_{NS} is negligible with respect to M_S , and T_{NS} is not close to T_S , the decoupling could be considered and the strategy for the analyses

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Fig. 3 (a) Cement industrial building. Machinery mounted upon an *rc* structure. (b) Cement Industrial Building Applications: Italy

could be oriented to the definition of the seismic action at the level of the connection, considering the structural system as a stand-alone element subjected to a seismic action at the base of it.

The following strategy can be considered: (a) time history analyses applied either to the whole system or to the stand-alone attachment, considering the acceleration histories recorded at the level of the attachment connection and (b) spectrum-based analyses defining an acceleration spectrum consistent with the time histories recorded at the points where the attachment is connected to the structures: the generated spectrum is usually named Floor Response Spectrum (FRS) even if (as the case reported in Fig. 4) the FRS has been evaluated where the attachment is linked and not at the floor level.

The FRS definition is an important task for the NSE analysis, being the referred analysis tool to be adopted, due to its recognized simplicity in conjunction with good level of reliability (in those cases where the decoupling can be adopted). It is possible to affirm that the usually adopted acceleration spectrum *is* to structural analysis *as* the FRS *is* to the analysis of nonstructural elements, so that the FRS is a period-dependent function that can be evaluated for different value of the attachment damping

given a specific soil and structure characterized by their own periods and dampings.

Differently from the secondary nonstructural elements, the secondary structural elements (SE) require different strategies of modeling and analysis. It is useful to introduce them as reported in CEN (2008): some structural elements (i.e., beams and columns) can be designed as seismic secondary elements, neglecting their contribution to the global seismic resistance so that their stiffness and strength can be neglected. As further specified in CEN (2008), the SE and the joint (that link them with structure) have to be designed considering (1) the vertical gravitational load, (2) displacement consequent to the seismic action, and (3) second-order effects that include the flexural moments evaluated considering the deformed element shape (P-Delta effect).

Clearly the previous definition of the SE supposes that they have a negligible influence in the global structural behavior.

Starting from the classification of the secondary elements in NSEs (attachments) and SEs, the following can be asserted: (1) given a construction, it includes a principal (P) and a secondary (S) structure; (2) if the S structure has a negligible influence on the P structure, the whole construction (PS) structural behavior can be decoupled; (3) the S structure can be classified in structural (SEs) and nonstructural (NSEs) elements; (4) the SEs have to be designed for vertical gravitational

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Fig. 4 FRS generation

load (transferred from the PS to them, including the self-weight loads) considering the seismic-induced displacement (P-Delta effect included); (5) the NSEs have to be verified with regard to self-weight loads and seismic action transmitted by the P structure; (6) the secondary structure elements and their supports (links) have to be verified in order to avoid that their partial or total failure can induce injury to people or important objects; and (7) if the interaction between P and S systems is not negligible, a global PS analysis is required.

In the following, some of the principal characteristic regarding secondary structural and nonstructural elements will be described.

Secondary Structural Elements

Typical case of SE is internal and external building partitioning system (Glass Systems included): their seismic contribution is usually neglected in the seismic analysis (1) accepting (for severe earthquake) their damage and (2) imposing that out-of-plane collapse (see Fig. 5) has to be prevented.

The infilled partitioning system can have a role in transferring the vertical load even if they can have a minor contribution in seismic global capacity. If they have no role in the vertical load as well as in the seismic P structure capacity, their classification as NSE (attachments) is reasonable.

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis,

Fig. 5 Molise (Italy): Seismic event occurred in 2002 (October 31 ($M = 5.4$) and November 1 ($M = 5.3$)). Example of damaged infilled frame: in-plane and out-of-plane mechanisms

If no flexible joints are considered (in between the P and S systems they represent), the absence of collaboration with the P system is not judicable by means of qualitative considerations, but it can require a structural analysis of the PS system including them as structural elements. In this case, the designer can follow some suggestions such as those included in CEN (2008) that consider a structural system as SE if its global stiffness is lower than 15 % of the P system stiffness. The models concerning the infilled frames systems are well known.

The damage level in the partitioning system is usually controlled imposing a threshold to the interstory drift (see Table 1) as function of the performance level and construction usage (ASCE 2002).

Attachments

Typical cases of attachments are parapets, windows, partitioning systems, antennas, electrical power systems, and furnitures. Depending on their components, they can be sensitive to the seismic acceleration or deformation (see Table 2).

Modeling and Analysis

NSEs are elements characterized by their mass and stiffness, and independently of the seismic action they are subjected to, they can be modeled and analyzed based on FEM strategies considering either their linear or nonlinear behavior.

In general the NSE is a system composed by subsystems with a structural complexity (see Fig. 6) that can require 3D complex models to be calibrated by means of experimental tests (Fig. 6a) including identification strategies: dynamic tests can be carried out by means of shaking tables (Fig. 6c).

The experimental tests in support of modeling and analysis implementation are especially required either when the importance of NSE usage is considered strategic or when the cost of it justifies the experimental activity. In some cases, a qualification procedure can be required, generally ruled by international standard (Gilani et al. 1999; IEEE 2005).

Modeling

Modeling has to take into account all the components that give stiffness and strength

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis, Table 1 Drift control: usually adopted values as function of usage and performance level

Performance level	Damage description and downtime/loss	Drift control
Immediate occupancy: usually required for construction which usage is considered strategic	Negligible structural damage; essential systems operational; minor overall damage. Downtime/loss: 24 h	0.3 % (stiff joint), 0.6 % (deformable joints)
Life safety	Probable structural and nonstructural damage; no collapse; minimal falling hazards; adequate emergency egress. Downtime/loss: possible total loss	0.5 % (stiff joint) 1.0 % (deformable joints)
Collapse prevention	Several structural and nonstructural damage; incipient collapse; probable falling hazards; possible restricted access. Downtime/loss: probable total loss	Not required

contributions, including the connection elements that, if needed, have to be modeled as nonlinear elements.

In many cases, such as the bushing sketched in Fig. 6a, an accurate modeling requires informations about all the subcomponents (coil springs, valves) in terms of mass stiffness and strength. The needed informations are not usually known and the element investigation has to be supported by means of experimental tests devoted either to global information acquisition (frequencies, modal shapes) or to evaluation of the level of

performance given a defined seismic action. Experimental tests can include shaking table tests or static tests: this aspect is strictly linked to the qualification process (IEEE 2005).

Seismic Action Modeling and Structural Analyses

Seismic action can be simulated according to the usually adopted strategies that, for the case at hand, include (1) time histories (usually in terms of acceleration) and (2) response spectrum finalized either to modal analyses or to static linear or nonlinear pushover analyses.

Seismic level will depend on the referred performance level that (see Table 1) identifies the required performance associable to a seismic event with a given return period, to be defined based on cost-benefit analysis.

General rules valid for secondary elements are the following:

1. Mass and stiffness uncertainties have to be considered together with spatial distribution of seismic effect in case of extended SE systems.
2. Seismic effects on SE have to take into account, in general, both horizontal and vertical components to be evaluated based on a structural model of the principal system.
3. If the SE behavior can be decoupled from the principal system, the datum method for the evaluation of the peak acceleration at the SE is based on the Floor Response Spectrum (FRS) that given an SE element, with a defined structural period and damping, attached to a given part of a structure, having its mechanical properties, subjected to a given seismic event (*E*), allows to define the peak acceleration to which the element will be subjected when the seismic event (*E*) is transferred at the base of NS element.

Based on the knowledge of the FRS, one of the following methods can be adopted: (a) static equivalent forces (including nonlinear pushover analysis), (b) modal analysis, and (c) time history (linear or nonlinear) analyses based on accelerograms compatible with the FRS.

Floor Response Spectra-Based Evaluation

Floor Response Spectra are functions that define the response spectrum of a given response parameter (e.g., acceleration, velocity, displacement) as a function of period and damping of a given structure (attachment) localized at a given point of the construction.

The generally adopted technique for the FRS definition consists in (1) analyzing the P structure (to which the S structure is attached) in the time domain, considering n time histories (e.g., acceleration TH), (2) evaluating (for each TH), at a given point of the structure, the TH of the acceleration and the related response spectrum for a given damping value, and (3) defining one representative spectrum (based on the n available FRSs) having a given overcoming probability (usually a 50 % probability is considered): for

low values of n (e.g., minor than 7), an envelope spectrum has to be considered.

Usually the location of the attachment is not known in advance, so that the previous procedure can be applied considering p points obtaining p Response Spectra. For those points that are located at the same level (*floor*) of the P structure, a single spectrum can be evaluated (enveloping the Response Spectra), naming it Floor Response Spectrum.

If the goal is the evaluation of conservative FRSs, for each floor, a set of points has to be opportunely selected so that both translational and rotational effects are captured: they usually include the floor centroids and one or more corners for each floor.

It is worth mentioning that having defined the P system structural model, it is possible to

Secondary Structures and Attachments Under Seismic Actions: Modeling and Analysis,

evaluate a transferring function H_p that (1) knowing the Fourier Transform (F_i , input FT) of a given accelerogram (2) allows the definition of the Fourier Transform of the TH acceleration at given point (F_o , output FT) so that (3) the inverse Fourier Transform of F_o gives the TH at the considered point that is the required information for the Response Spectrum evaluation.

Alternatively, if the Power Spectrum G_i of a given earthquake or of a family of earthquakes is known as well as the previous defined Input Transferring Function (F_i), the output Power Spectrum (G_o) is evaluable according to Eq. 1.

$$G_o(w) = G_i(w) |H_p(w)|^2 \quad (1)$$

Knowing $G_o(w)$ and the transferring function (H_{SDOF}) of a single-degree-of-freedom system (SDOF), the SDOF Spectra Power Density is evaluable (see Eq. 2) and the related Response Spectrum is the required FRS.

$$G_{SDOF}(w) = G_o(w) |H_{SDOF}(w)|^2 \quad (2)$$

The previously presented approaches are not usually adopted for conventional structures as they are time consuming, so that predictive expressions are proposed in literature or enforced in

international recommendations: given the peak ground acceleration, the floor peak acceleration is evaluated by multiplying the PGA by an analytical function, named S_a in the following.
